The most common toxicities for thalidomide include somnolence, constipation, dizziness, orthostatic hypotension, rash, and peripheral neuropathies. In contrast, lenalidomide is associated with much less somnolence and neuropathies compared with thalidomide. Neutropenia, thrombocytopenia, and thrombotic events are common with thalidomide, lenalidomide, and pomalidomide. To avoid embryo-fetal exposure and inform healthcare professionals and patients of the teratogenic potential, these agents are only available through a risk evaluation and mitigation strategy (REMS) program.

TARGETED AGENTS: SMALL MOLECULES

⑥ Small-molecule targeted agents (molecular weight less than 1,000 Da) are typically identified as kinase inhibitors. Kinases are enzymatic proteins that constitute the intracellular signaling pathways, such as the JAK-STAT and MAPK/ERK pathways described earlier. Following ligand binding to an extracellular receptor, kinases transmit signals to the cell interior that stimulates activation of the pathway. The small-molecule targeted agents turn off or inhibit these pathways by inhibiting the adenosine triphosphate (ATP) binding domain of the kinases. Most of the approved kinase inhibitors inhibit more than one kinase. The binding to multiple kinases typically leads to off-target effects or toxicities; some toxicities are attributed to specific kinase families. Although most inhibitors are given orally continuously for months to years, their anticancer activity is typically limited by the development of resistance. Before initiating therapy, some targeted drugs require identification of the target within the tumor using a companion or complementary diagnostic test. Of note, most kinase inhibitors and mAbs are associated with a warning for embryo-fetal toxicity. The individual product labeling should be referenced for contraception guidelines in females of reproductive potential and males with female partners of reproductive potential.

Anaplastic Lymphoma Kinase (ALK) Inhibitors

Crizotinib

Crizotinib binds to the ATP intracellular domain of activated ALK, thereby inhibiting phosphorylation and subsequent downstream signaling. ALK rearrangements were first identified in large cell lymphomas and later in NSCLC. In NSCLC, the most common rearrangement involves inversion of chromosome 2p that is primarily fused to the echinoderm microtubule-like protein 4 (EML4), which forms the ALK-EML4 oncogene fusion protein. This rearrangement leads to the activation of downstream signaling pathways and inhibition of apoptosis. ALK-EML4 has a higher prevalence in younger patients, never or light smokers, and adenocarcinoma histology. Crizotinib also inhibits other kinases, such as ROS1, RON, and mesenchymal-epithelial transition (MET). Crizotinib is approved for the treatment of patients with metastatic NSCLC that is ALK or ROS1-positive and for ALK-positive anaplastic large cell lymphoma.

The most common toxicities reported in patients taking crizotinib include nausea, vomiting, diarrhea, constipation, fatigue, and elevated transaminases. Visual disorders occur in about half of patients and usually occur within the first weeks of therapy. Edema is also commonly seen and is most likely attributed to the inhibition of MET. Crizotinib has been associated with interstitial lung disease/pneumonitis, hepatotoxicity, QTc interval prolongation, and bradycardia.

Many patients with ALK-positive NSCLC initially respond to crizotinib. Still most patients will develop resistance possibly related to the development of brain metastases or genetic alterations in ALK. The L1196M mutation has been recently identified as a mechanism of crizotinib resistance.

Alectinib, Brigatinib, and Ceritinib

Alectinib, brigatinib, and ceritinib are second-generation ALK inhibitors approved for the treatment of patients with metastatic ALK-positive NSCLC. Similar to crizotinib, these agents inhibit autophosphorylation of ALK and subsequent downstream signaling. In addition to ALK, ceritinib also inhibits insulin-like growth factor 1 receptor, although to a lesser extent.[22]

Toxicities that are seen with both alectinib and ceritinib include fatigue, bradycardia, and hepatotoxicity. Additional adverse drug reactions seen in patients taking alectinib include anemia, constipation, edema, and myalgia. Brigatinib has been associated with pulmonary toxicities and bradycardia. Patients taking ceritinib should be monitored for QTc interval prolongation, gastrointestinal toxicity, pancreatitis, and hyperglycemia. Visual disturbances have been reported with second-generation ALK inhibitors, although to a much lesser extent. While crizotinib and brigatinib may be taken without regard to food, alectinib should be taken with food. Of note, ceritinib was previously recommended at a higher dose administered on an empty stomach, but the currently approved dose is lower and is to be taken with food to improve gastrointestinal tolerability. To decrease the risk of early onset pulmonary toxicities, a dose-escalation approach must be used with brigatinib.

Lorlatinib

A third-generation ALK and ROS1-inhibitor, lorlatinib, is approved for the treatment of ALK-positive NSCLC. It has demonstrated activity in the first-line setting and following progression on one or more ALK inhibitors.[23] Similar to other agents in this category, lorlatinib is associated with hepatotoxicity and interstitial lung disease/pneumonitis. CNS toxicities, hyperlipidemia, and atrioventricular block have also been reported.

BCL-2 Inhibitor

Venetoclax is a selective inhibitor of BCL-2, an antiapoptotic protein overexpressed in CLL. Permeabilization of the mitochondrial membrane, with the help of mediators BAX and BAK, is the last step in the apoptosis pathway. BCL2 constrains BAX and BAK, resulting in CLL cells resistant to apoptosis.[24] Venetoclax binds directly to the BCL-2 protein restoring the apoptotic process. It is approved for the treatment of patients with CLL, small lymphocytic lymphoma, and newly diagnosed AML in adults who are unable to receive intensive induction chemotherapy (eg, age 75 years or older). Reported toxicities associated with venetoclax include myelosuppression, fatigue, diarrhea, cough, and upper respiratory tract infection. To reduce the risk of TLS, a weekly dose escalation over the first 5 weeks is required, and patients should receive antihyperuricemic agents and hydration. Oral administration of venetoclax should be with food.

Breakpoint Cluster Region-Abelson (BCR-ABL) Inhibitors

Imatinib

Imatinib is a selective inhibitor of the *bcr-abl* fusion gene, the product of the Philadelphia chromosome (Ph). The Ph chromosome is the hallmark finding of CML, and it is a translocation of genetic material between chromosomes 9 and 22. Imatinib binds to the kinase-binding site of the *bcr-abl* gene, competitively blocking access to ATP. This prevents tyrosine-kinase phosphorylation of the gene and downstream activation of cellular proliferation. An additional effect of imatinib is its ability to inhibit stem-cell factor receptor (KIT) and PDGF receptor (PDGFR).

Imatinib is a standard treatment option for newly diagnosed Ph positive (Ph+) CML and gastrointestinal stromal tumors (GIST). A major advantage of imatinib is that it can eliminate the Ph, resulting in cytogenetic responses (ie, elimination of the genetic defect). Imatinib and other BCR-ABL inhibitors are further discussed in Chapter 158, “Chronic Leukemias.” Imatinib is also approved for the treatment of Ph^+ALL and other rare diseases.

Potential serious adverse drug reactions observed with imatinib include fluid retention and rash. Severe fluid retention (ie, pleural effusion, pericardial effusion, and ascites) occurs in fewer than 10% of patients taking imatinib, but patients should be monitored regularly for early signs and symptoms of fluid retention and instructed to call their health professionals when symptoms first develop. Additionally, a rash may require early intervention because Stevens-Johnson syndrome has been reported.

Dasatinib, Nilotinib, and Bosutinib

The second-generation kinase inhibitors dasatinib, nilotinib, and bosutinib share the same binding site on the BCR-ABL kinase ATP-binding domain with imatinib. These inhibitors maintain clinical activity in patients with CML with some mutations in the BCR-ABL binding site that confer imatinib resistance. Still, none of these inhibitors are active against the genetic alteration identified as T315I. Dasatinib is approved for the treatment of Ph^+CML and Ph^+ALL. Nilotinib and bosutinib are approved for the treatment of Ph^+CML. Both bosutinib and dasatinib also inhibit a family of kinases called sarcoma kinases that are believed to mediate cellular differentiation, proliferation, and survival; sarcoma kinases have been implicated in modulating multiple oncogenic signal transduction pathways.

These second-generation agents have a toxicity profile similar to that of imatinib, with myelosuppression, nausea, vomiting, headache, and fluid retention being commonly reported. Bosutinib does not inhibit KIT or PDGFR, which may account for its reported decrease in the incidence of myelosuppression.

Ponatinib

As mentioned earlier, the T315I mutation, often referred to as the gatekeeper mutation, confers resistance to the above BCR-ABL inhibitors. Ponatinib, a third-generation agent, was developed to inhibit this mutated conformation of BCR-ABL and provide an effective treatment for this traditionally resistant tumor. Ponatinib is approved for the treatment of Ph^+ALL and Ph^+CML in patients for whom no other kinase inhibitors are indicated, such as those with a T315I mutation. Common toxicities are similar to other BCL-ABL inhibitors, such as hypertension, rash, headache, constipation, fever, and nausea. Arterial thrombosis and hepatotoxicity have also been observed.

BRAF Inhibitors

BRAF is mutated in a variety of solid tumors, with most mutations occurring at codon 600. This codon is in the activation loop of BRAF and increases downstream activity at MEK then ERK, which results in proliferation and survival of cancer cells. BRAF is altered in approximately 65% of papillary thyroid carcinomas, 35% of melanomas and anaplastic thyroid carcinomas, 11% of colorectal cancers, and 5% of NSCLC.[25] The most common BRAF mutations in melanomas are the V600E mutation, which replaces valine with glutamic acid at codon 600 (~80% of cases), and the V600K mutation, which replaces valine with lysine (~8% of cases). Dabrafenib, encorafenib, and vemurafenib inhibit BRAF V600, thereby blocking the MAPK pathway in BRAF-mutated cells.

For patients with BRAF-mutated melanoma, combination therapy with a BRAF and MEK inhibitor has been associated with improved outcomes, so doublet therapy is given in clinical practice: dabrafenib with trametinib, encorafenib with binimetinib, and vemurafenib with cobimetinib. Dabrafenib is approved for V600E and V600K mutated melanoma, V600E NSCLC, and V600E anaplastic thyroid cancer. Vemurafenib is approved for melanoma with a V600E mutation and for the treatment of Erdheim-Chester disease with a V600 mutation. Encorafenib is approved for melanoma with a V600E or V600K mutation (in combination with binimetinib) and for patients with colorectal cancer with a BRAF V600E mutation (in combination with cetuximab).

Toxicities associated with all BRAF inhibitors either as monotherapy or in combination with a MEK inhibitor include uveitis, arthralgia, fatigue, and nausea. Patients should be monitored for the development of new cutaneous malignancies and noncutaneous squamous cell carcinoma associated with the dabrafenib-, encorafenib- and vemurafenib-induced paradoxical activation of the MAPK pathway.[26] PPE and pyrexia are commonly seen with dabrafenib, whereas QTc prolongation is more commonly reported with encorafenib and vemurafenib. Vemurafenib is also associated with severe dermatologic reactions and photosensitivity.

Bruton's Tyrosine Kinase (BTK) Inhibitors

BTK is involved in the B-cell receptor signaling pathway that leads to B-cell proliferation and differentiation upon its activation. In B-cell malignancies, the B-cell receptor signaling pathway promotes disease progression, although the exact mechanism of B-cell receptor stimulation has not been determined. The first-generation BTK inhibitor, ibrutinib, forms an irreversible covalent bond with a cysteine residue of BTK, resulting in the inhibition of malignant B-cell proliferation and survival. Ibrutinib is approved for the treatment of chronic graft-versus-host disease and the following B-cell malignancies: Waldenstrom's macroglobulinemia; mantle cell lymphoma; marginal zone lymphoma; and CLL. Acalabrutinib is approved for both CLL and mantle cell lymphoma while zanubrutinib is only approved for mantle cell lymphoma. Although the frequency of adverse drug reactions varies between BTK inhibitors, patients should generally be monitored for hemorrhage, infections, cytopenias, cardiovascular effects (eg, atrial fibrillation), and TLS. Additional common toxicities include diarrhea, fatigue, musculoskeletal pain, nausea, and rash.

CDK Inhibitors

As discussed earlier in this chapter, CDKs play an important role in cell-cycle progression. Specifically, CDK 4/6 and cyclin D1 regulate transition from the G_1 phase to the S phase by phosphorylating the retinoblastoma protein. Palbociclib, ribociclib, and abemaciclib inhibit CDK 4/6, resulting in the blockade of retinoblastoma protein hyperphosphorylation and ultimately G_1 arrest.[27] In breast cancer, it has been demonstrated that cyclin D1 expression and subsequent retinoblastoma protein phosphorylation can be maintained despite estrogen receptor (ER) antagonism. Therefore, inhibiting CDK 4/6 may overcome acquired resistance to hormonal therapy observed in ER-positive breast cancer.[27]

Palbociclib, ribociclib, and abemaciclib are approved for use in ER-positive, HER2-negative advanced, or metastatic breast cancer in combination with an aromatase inhibitor in postmenopausal patients. Additionally, palbociclib and abemaciclib are approved in combination with fulvestrant after failure of endocrine therapy, and abemaciclib is approved as monotherapy in this population following progression on endocrine therapy and chemotherapy. Patients receiving these agents should be monitored for hematologic toxicities, infections, and pulmonary embolisms. Ribociclib has been associated with concentration-dependent QTc prolongation, so electrocardiograms (ECGs) and electrolytes should be regularly monitored.

Colony-Stimulating Factor-1 Receptor Inhibitors

Tenosynovial giant cell tumors are rare malignancies that often arise from the joints, bursae, or tendon sheaths and may be associated with significant morbidity and functional limitations.[28] These tumors are characterized by the overexpression of colony-stimulating factor–1 receptor ligand that promotes cell proliferation and accumulation in the synovium. Pexidartinib inhibits colony-stimulating factor–1 receptor and is approved for the treatment of select patients with tenosynovial giant cell tumors. However, due to the severe risk of hepatotoxicity, pexidartinib is only available through a REMS program. Pexidartinib is also associated with many known drug-drug interactions.

EGFR Inhibitors

Erlotinib

Erlotinib is an oral first-generation selective EGFR kinase inhibitor. By competing with ATP for its binding site on the EGFR kinase cytosolic domain, it blocks intracellular downstream signaling and ultimately interferes with the proliferation and growth of cancer cells. Erlotinib is approved for patients with metastatic NSCLC whose tumors have EGFR exon 19 deletions or exon 21 (L858R) substitution mutations detected by an FDA-approved test. Erlotinib is also approved for use in pancreatic cancer in combination with gemcitabine.

The most common adverse drug reactions that occur with erlotinib result from the abundance of EGFR in skin and mucosa and include acneiform rash and diarrhea. Some studies suggest that the development of a rash may be predictive of a response to therapy and correlates with clinical benefit.[29] Interstitial lung disease is a rare adverse drug reaction reported in patients taking erlotinib.

Afatinib and Dacomitinib

Unlike erlotinib which reversibly binds to EGFR, afatinib and dacomitinib irreversibly block all kinases of the ErbB family by covalently binding to the intracellular kinase domain which subsequently inhibits tumor growth. Afatinib is approved for the treatment of patients with EGFR mutation-positive NSCLC and previously treated squamous NSCLC. Dacomitinib is approved for the first-line treatment of patients with metastatic NSCLC harboring an EGFR exon 19 deletion or exon 21 (L858R) substitution mutation. Adverse drug reactions observed with afatinib and dacomitinib are similar to those reported with erlotinib.

Gefitinib

Gefitinib similarly blocks the promotion of the development of lung cancer cells with specific EGFR mutations (exon 19 deletions and exon 21 substitution). It is approved for the first-line treatment of metastatic NSCLC, whose tumors harbor specific EGFR gene mutations, based on the results of a clinical trial that demonstrated an improvement in response in this specific population. Gefitinib has similar adverse drug reactions compared to other EGFR inhibitors, including diarrhea and skin reactions.

Osimertinib

Osimertinib is approved for the treatment of patients with metastatic NSCLC whose tumors harbor EGFR exon 19 deletions or exon 21 L858R mutations, as detected by an FDA-approved test. It is also indicated for EGFR T790M mutation-positive NSCLC after disease progression on or after an EGFR inhibitor. The T790M mutation, also referred to as the EGFR gatekeeper mutation, occurs in about 50% of patients who develop acquired resistance to first-line therapy with erlotinib or gefitinib.[30] Gastrointestinal and dermatologic toxicities are commonly reported with osimertinib. Serious adverse drug reactions include interstitial lung disease/pneumonitis, pneumonia, and pulmonary embolism.

Enhancer of Zest Homolog 2 (EZH2) Inhibitors

EZH2 is overexpressed or mutated in many malignancies, including follicular lymphoma and various solid tumors. Tazemetostat, a selective inhibitor of histone methyltransferase EZH2, is approved for the treatment of patients with epithelioid sarcoma. It is also indicated for patients with follicular lymphoma that is EZH2 mutation-positive or for those with no satisfactory alternative treatment options. It is commonly associated with fatigue and gastrointestinal adverse drug reactions. Secondary malignancies, including T-cell lymphoblastic lymphoma, MDS, and AML, have also been associated with the use of tazemetostat.

Fibroblast Growth Factor Receptor (FGFR) Inhibitors

The FGFR pathway regulates numerous physiological processes, including embryogenesis, wound healing, inflammation, and angiogenesis.[31] Alterations occur in approximately 7% of solid tumors, and multiple oral FGFR inhibitors are currently approved for use. Erdafitinib is a pan-FGFR inhibitor (FGFR1-4) approved for the treatment of patients with urothelial carcinoma with a susceptible FGFR3 or FGFR2 alteration. Infigratinib, also a pan-FGFR inhibitor, is indicated for the treatment of patients with cholangiocarcinoma with an FGFR2 fusion. Pemigatinib inhibits FGFR 1, 2, and 3, and is approved for the treatment of patients with cholangiocarcinoma with an FGFR2 fusion. Serious ocular disorders have been reported with all agents. Interestingly, elevated phosphate levels are common with FGFR inhibitors as the FGFR pathway is involved in a sodium-dependent phosphate cotransporter in the proximal renal tubule. Monitor phosphate levels closely and adjust or hold treatment according to the guidance provided in the prescribing information.

FMS-Like Tyrosine Kinase-3 (FLT3) Inhibitors

FLT3 is one of the most common mutations in AML and is known to play a role in the normal growth and differentiation of hematopoietic precursor cells. FLT3 mutations can be divided into internal tandem duplications or point mutations of the activation loop of the tyrosine kinase domain.

Midostaurin inhibits multiple receptors, including FLT3 mutant kinases, resulting in apoptosis of leukemic cells. It is indicated in combination with cytotoxic chemotherapy for the treatment of FLT3-positive AML. Other indications include mast cell leukemia and systemic mastocytosis. Adverse drug reactions reported with midostaurin include pulmonary toxicity, febrile neutropenia, gastrointestinal toxicities, fatigue, and hyperglycemia.

Similarly, gilteritinib inhibits multiple receptors including FLT3. It is a second-generation agent indicated for the treatment of adult patients who have relapsed or refractory AML with a FLT3 mutation. Patients taking gilteritinib must be monitored for differentiation syndrome, QTc prolongation, pancreatitis, posterior reversible encephalopathy syndrome, and creatine phosphokinase elevation. Other common adverse drug reactions include edema, stomatitis, rash, and elevated serum transaminases. Both midostaurin and gilteritinib are oral agents; midostaurin should be administered with food, whereas gilteritinib may be administered without regard to food. Fedratinib is another FLT3 inhibitor but will be discussed later in the chapter with the JAK inhibitors.

HDAC Inhibitors

The mechanism of HDAC inhibitors was discussed earlier in the chapter. Belinostat is an HDAC inhibitor that is approved for the treatment of relapsed or refractory peripheral T-cell lymphoma. The most common toxicities reported with belinostat include pyrexia, nausea, fatigue, and anemia.

Panobinostat is an HDAC inhibitor that has been shown to improve progression-free survival with bortezomib and dexamethasone in patients with multiple myeloma who have received at least two prior regimens, including bortezomib and an immunomodulatory agent.[32] Since severe cardiac toxicities and QTc prolongation have been reported with panobinostat, an ECG and electrolytes should be monitored at baseline and during treatment. Nausea, vomiting, and severe diarrhea are often seen with panobinostat.

Similar to belinostat and panobinostat, romidepsin and vorinostat inhibit HDAC. Romidepsin is approved for the treatment of cutaneous or peripheral T-cell lymphoma who have received at least one prior therapy, and vorinostat is approved for patients with cutaneous T-cell lymphoma who have received at least two prior therapies. Patients receiving romidepsin should be monitored for myelosuppression, ECG changes, and infections. Reactivation of DNA viruses, including Epstein Barr virus and hepatitis B virus (HBV), have been reported with romidepsin. Additional serious adverse drug reactions reported with vorinostat include venous thromboembolism (VTE), dose-related thrombocytopenia, and anemia.

Hedgehog Inhibitors

Sonidegib, vismodegib, and glasdegib are oral inhibitors of the Hedgehog signaling pathway that is abnormally activated in basal cell carcinoma, medulloblastoma, and leukemias. Through binding to smoothened, or SMO receptor, these agents prevent downstream signaling and activation of the Hedgehog pathway leading to the inhibition of tumor growth.

The Hedgehog pathway is essential for early embryogenesis. Therefore, sonidegib, vismodegib, and glasdegib can cause embryotoxicity, fetotoxicity, and teratogenicity. The approved labeling for these drugs contains specific recommendations regarding contraception for patients of child-bearing potential and for patients with a pregnant partner or a partner of child-bearing potential, as well as limitations regarding blood and sperm donation during treatment and for several months following the last dose.

Vismodegib is approved for metastatic or locally advanced basal cell carcinoma, while sonidegib is approved only for locally advanced disease. Vismodegib is generally well tolerated, and toxicities include muscle spasm, alopecia, dysgeusia, fatigue, and nausea. Sonidegib is associated with an increased risk of serious musculoskeletal toxicities, and the probability of developing this adverse drug reaction appears to rise with increasing sonidegib exposure. Grades 3 and 4 serum lipase and creatine kinase elevations have also been reported. Sonidegib uniquely has a very long elimination half-life of 28 days compared to vismodegib and other small-molecular targeted agents.

Glasdegib is given in combination with low-dose cytarabine and is indicated for the treatment of newly diagnosed AML in patients 75 years of age or older or for those with comorbidities that preclude intensive induction chemotherapy. Similar to vismodegib and sonidegib, muscle spasms and fatigue have been reported with glasdegib. QTc prolongation may occur so ECGs and electrolytes should be monitored while on treatment.

HER2 Inhibitors

Lapatinib is a 4-anilinoquinazoline kinase inhibitor that inhibits the intracellular kinase domains of both EGFR (ErbB1) and HER2 (ErbB2). It has demonstrated clinical activity with capecitabine in patients with previously treated breast cancer whose tumors overexpress HER2. Lapatinib is also approved for use with letrozole in postmenopausal patients for the treatment of hormone receptor–positive metastatic breast cancer that overexpresses HER2. Warnings associated with lapatinib include reduced LVEF, interstitial lung disease, diarrhea, rash, and QTc prolongation in addition to a boxed warning for hepatotoxicity. Two specific mutations observed in the HLA-DQA and HLA-DRB genes have been associated with an increased risk of hepatotoxicity.[33]

In addition to EGFR and HER2, neratinib irreversibly inhibits HER4 and is approved for HER2-positive breast cancer. Diarrhea is the most common toxicity associated with neratinib, and antidiarrheal prophylaxis is recommended during the first two treatment cycles. Patients should be monitored for gastrointestinal toxicities, fatigue, dehydration, and hepatotoxicity.

Unlike lapatinib and neratinib, tucatinib is selective for HER2 inhibition but has minimal effects on EGFR. It is approved for HER2-positive breast cancer in combination with trastuzumab and capecitabine. Serious adverse drug reactions associated with tucatinib are similar to lapatinib and neratinib and include diarrhea and hepatotoxicity. Additionally, tucatinib may cause a “false” elevation in serum creatinine resulting from the inhibition of proximal tubule transporters which reduces creatinine secretion. This increase in serum creatinine does not affect glomerular filtration and is reversible upon treatment discontinuation.

IDH Inhibitors

As discussed earlier in the chapter, IDH mutations are associated with impaired cellular differentiation in about 15% to 20% of patients with AML. Ivosidenib and enasidenib are approved for the treatment of AML with a susceptible IDH1 or IDH2 mutation, respectively. Nausea, vomiting, diarrhea, and elevated serum bilirubin have been reported with enasidenib. Common toxicities associated with ivosidenib include nausea, mucositis, rash, and leukocytosis. Warnings for ivosidenib include QTc prolongation and Guillain-Barré syndrome. Differentiation syndrome, as discussed above with arsenic trioxide, is a potentially fatal complication associated with both IDH inhibitors.

JAK Inhibitors

Ruxolitinib is an oral inhibitor of JAK1 and JAK2 of the JAK-STAT signaling pathway; these kinases are involved in the regulation of blood and immunologic functioning. In myelofibrosis and polycythemia vera, JAK1 and JAK2 activity is dysregulated. Ruxolitinib has been shown to modulate the affected JAK1 and JAK2 activity resulting in clinical responses and symptomatic improvement. Approved indications for ruxolitinib include the treatment of intermediate- or high-risk myelofibrosis and the treatment of polycythemia vera in patients who have had an inadequate response to or are intolerant of hydroxyurea. It is also approved for acute, corticosteroid-refractory graft-versus-host disease. The most common toxicities include thrombocytopenia, anemia, bruising, dizziness, and headache. Caution must be used when stopping ruxolitinib as severe cases of withdrawal syndrome have been reported.

While ruxolitinib inhibits both JAK1 and JAK2, fedratinib has a higher affinity for JAK2. Fedratinib is approved for myelofibrosis. The product labeling includes a boxed warning for encephalopathy so thiamine should be assessed and repleted at baseline and periodically throughout treatment. Additional adverse drug reactions associated with fedratinib include hematologic toxicities, gastrointestinal toxicities, and hepatotoxicity.

MEK Inhibitors

Reported resistance mechanisms of the BRAF inhibitors dabrafenib, encorafenib, and vemurafenib include reactivation of the MAPK pathway. The combination of BRAF and MEK inhibition has demonstrated delayed resistance in melanoma and decreased incidence of secondary cancers. MEK inhibitors, including binimetinib, cobimetinib, and trametinib, are given in combination with a BRAF inhibitor, and their indications in BRAF V600 mutated tumors are discussed above. Severe toxicities associated with MEK inhibitors include cardiomyopathy and hemorrhage. Rhabdomyolysis and hepatotoxicity have been reported with binimetinib and cobimetinib. Additionally, VTE and interstitial lung disease have been associated with binimetinib and trametinib.

Unlike the other agents in this class, selumetinib has not demonstrated success in early trials with BRAF-mutated tumors. However, selumetinib has shown tumor shrinkage and clinical benefit in children with neurofibromatosis type 1, a rare genetic disorder associated with peripheral-nerve sheath tumors known as plexiform neurofibromas.[34] Inhibition of MEK has proven successful since overactivation of the RAS pathway has been associated with neurofibromatosis type 1. Common toxicities are similar to other MEK inhibitors and include nausea, vomiting, diarrhea, increased creatine phosphokinase, rash, and paronychia. Interestingly, selumetinib capsules contain vitamin E, and, therefore, its use comes with a warning regarding increased vitamin E levels and risk of bleeding.

MET Inhibitors

The MET gene is a proto-oncogene associated with tumor cell growth and survival. MET Exon 14 skipping results in aberrant downstream signaling from the MET receptor resulting in tumor invasion, migration, and metastasis. Alterations in MET are reported in approximately 3% of solid tumors, including NSCLC. Both capmatinib and tepotinib inhibit the MET signaling pathway and are approved for patients with NSCLC harboring a MET Exon 14 skipping alteration. Hepatotoxicity and interstitial lung disease have been reported in clinical trials with capmatinib and tepotinib. Additionally, capmatinib has been associated with photosensitivity so patients should be instructed to limit ultraviolet exposure during treatment.

mTOR Inhibitors

Temsirolimus and its primary active metabolite, sirolimus, bind to the intracellular protein 12-kilodalton FK506 binding protein 12 and this protein–drug complex inhibits mTOR by blocking its kinase activity. mTOR inhibition suppresses the production of proteins that regulate progression through the cell cycle resulting in G_1-phase arrest. Temsirolimus is administered via IV infusion and is approved for the treatment of advanced renal cell carcinoma.

The most common adverse drug reactions with temsirolimus are rash, asthenia, mucositis, nausea, edema, and anorexia. Infusion reactions may occur and pretreatment with an antihistamine is recommended. Metabolic abnormalities are common with temsirolimus, including hyperglycemia and hyperlipidemia. Rare but potentially serious toxicities include interstitial lung disease, immunosuppression, and renal failure.

Similar to temsirolimus, everolimus is an mTOR inhibitor that reduces protein synthesis and cell proliferation by binding to FK506 binding protein 12. Everolimus is administered orally and has the following indications: advanced renal cell carcinoma; hormone receptor–positive, HER2-negative breast cancer with exemestane in postmenopausal patients; subependymal giant cell astrocytoma with tubular sclerosis complex; renal angiomyolipoma with tubular sclerosis complex; and pancreatic, gastrointestinal, and lung neuroendocrine tumors. Dosage forms for everolimus include traditional oral tablets and tablets for oral suspension, but it is important to note that the indications differ depending on formulation. Stomatitis is one of the most common toxicities with everolimus, and other adverse drug reactions are similar to those of temsirolimus.

Nuclear Export Inhibitor

Selinexor is a first-in-class nuclear export inhibitor approved for patients with treatment-refractory diffuse large B-cell lymphoma and multiple myeloma. Through binding to exportin-1, selinexor inhibits nuclear export resulting in the retention of tumor suppressor proteins in the nucleus and the prevention of oncoprotein messenger RNA translation.[35] Exportin-1 is overexpressed in many cancer cells and has been associated with the development of resistance to anticancer agents.

Patients receiving selinexor should be monitored for thrombocytopenia, neutropenia, gastrointestinal toxicities, and hyponatremia. Additionally, infections are commonly reported and may include upper respiratory infection, pneumonia, and sepsis. Patients should be counseled on the potential neurotoxicity associated with selinexor, which may include syncope, hallucinations, amnesia, and mental status changes, among others.

PARP Inhibitors

PARP is essential for the repair of single-stranded DNA breaks through the base-excision-repair pathway. Tumors with breast cancer gene 1 (*BRCA1*) or *BRCA2* mutations are highly sensitive to the accumulation of single-strand DNA breaks because they exhibit a compromised ability to repair double-strand DNA breaks. Typically, double-strand DNA breaks are repaired through the homologous recombination repair pathway which involves proteins such as *BRCA1* and *BRCA2*. When tumors have deficiencies in homologous recombination repair (through a *BRCA* or other mutation), they lack the ability to repair DNA damage and are therefore more susceptible to the effects of PARP inhibition. This concept is known as *synthetic lethality* and occurs when there is a lethal synergy between two nonlethal events.[2] Four PARP inhibitors are currently available and their corresponding FDA-approved indications are as follows: niraparib is approved for ovarian, fallopian tube, or primary peritoneal cancers; olaparib is approved for *BRCA*-mutated, HER2-negative breast cancer, *BRCA*-mutated ovarian cancer, homologous recombination deficient-positive ovarian cancer, *BRCA*-mutated pancreatic cancer, and homologous recombination repair gene-mutated prostate cancer; rucaparib is approved for *BRCA*-mutated ovarian cancer and *BRCA*-mutated prostate cancer; and talazoparib is approved for *BRCA*-mutated, HER2-negative locally advanced or metastatic breast cancer.

As a class, these agents are commonly associated with anemia, fatigue, and nausea. Secondary malignancies of MDS/AML have been reported. Similar to tucatinib described earlier in the chapter, olaparib and rucaparib are commonly associated with a “false” elevation in serum creatinine. Niraparib is more often associated with thrombocytopenia and hypertension, whereas transaminase elevation is most commonly seen with rucaparib and talazoparib. Talazoparib is also associated with myelosuppression.

PDGFR-α Inhibitors

PDGFR-α belongs to a family of growth factors that act as mitogens (peptides that induce cell division) for cells of mesenchymal origin and is a hallmark of GIST. Signaling of this pathway results in differentiation, growth, and angiogenesis. Ripretinib and avapritinib are oral PDGFR-α inhibitors. Ripretinib is approved for the treatment of refractory GIST and avapritinib is approved for the treatment of GIST harboring a PDGFR- α Exon 18 mutation and advanced systemic mastocytosis. In addition to inhibiting PDGFR, ripretinib also inhibits BRAF and VEGFR, which are reflected in its toxicity profile. Ripretinib has been associated with cutaneous malignancies (including squamous cell carcinoma and melanoma), hypertension, cardiac dysfunction, PPE, and impaired wound healing. Warnings for avapritinib include intracranial hemorrhage and CNS effects.

PI3K Inhibitors

Malignant B-cell proliferation and survival depend on PI3K signaling. The p110δ isoform is highly expressed in malignant lymphoid B-cells and plays a direct role in activation of the PI3K pathway. The four PI3K inhibitors that are approved for hematologic indications have different affinities for the PI3K isoforms: idelalisib primarily inhibits p110δ; duvelisib inhibits p110δ and p110γ; copanlisib preferentially targets p110α and p110δ; and umbralisib primarily targets p110δ.[36,37] Idelalisib is an oral agent approved for the treatment of relapsed CLL (in combination with rituximab), follicular B-cell NHL, and small lymphocytic lymphoma. Duvelisib is an oral agent indicated for relapsed or refractory CLL, small lymphocytic lymphoma, and follicular lymphoma. Copanlisib, the only intravenously administered PI3K inhibitor, is indicated for relapsed follicular lymphoma. Umbralisib, the most recently approved oral PI3K inhibitor, also inhibits casein kinase 1 epsilon (thought to be involved in the pathogenesis of lymphoid malignancies) and is indicated for the treatment of relapsed or refractory follicular lymphoma and marginal zone lymphoma. In solid tumors, mutations in the p110α subunit of PI3K result in dysregulation of the PI3K/mTOR pathway.[38] Alpelisib, an oral PI3Kα-selective inhibitor, is the only PI3K inhibitor approved for the treatment of a solid tumor: PI3KCA-mutated, hormone receptor–positive, HER2-negative breast cancer (in combination with fulvestrant).

Serious adverse drug reactions are associated with these agents. Duvelisib has a REMS program to increase awareness and mitigate the risks of infections, diarrhea/colitis, cutaneous reactions, and pneumonitis. Similarly, idelalisib has a REMS program for hepatotoxicity, diarrhea/colitis, pneumonitis, and intestinal perforation. *P. jirovecii* pneumonia prophylaxis should be administered during treatment with duvelisib, idelalisib, umbralisib, and considered for patients receiving copanlisib. Antiviral prophylaxis to prevent cytomegalovirus infection should also be considered in select patients. Both alpelisib and copanlisib have been associated with hyperglycemia. Serious hypertension, including infusion-related hypertension, has been commonly reported with copanlisib. Umbralisib holds a warning for allergic-type reactions due to Yellow No. 5 which is contained in the dosage form.

Proteasome Inhibitors

The proteasome is an enzyme complex that is responsible for degrading proteins that control the cell cycle. Some of the proteins degraded by proteasomes regulate critical functions for cancer growth, such as regulation of the cell cycle, transcription factors, apoptosis, angiogenesis, and cell adhesion.

Bortezomib reversibly inhibits the 26S proteasome resulting in accumulation of IκB, an inhibitor of the major transcription factor nuclear factor κB (NF-κB). NF-κB induces transcription of genes that block cell death pathways and promote cell proliferation. Its activity depends on its release from its inhibitory partner protein, IκB, in the cytoplasm and its move to the nucleus. When IκB fails to degrade, through the actions of bortezomib, NF-κB remains in the cytoplasm, preventing it from transcribing the genes that promote cancer growth. Bortezomib is approved for the treatment of multiple myeloma and mantle cell lymphoma.

The most commonly reported toxicities with bortezomib include fatigue, nausea, diarrhea, thrombocytopenia, and fever. Peripheral neuropathy may develop or worsen with the use of bortezomib. Subcutaneous administration of bortezomib has been associated with a lower incidence of severe peripheral neuropathy when compared with intravenous administration. Caution should be used when treating patients with existing heart disease as cardiac failure has been reported. Patients should also be monitored for hypotension and acute respiratory syndrome. At least 72 hours should elapse between consecutive doses of bortezomib to minimize cumulative toxicity by permitting the restoration of proteasome function between doses. Proteasome inhibitors are associated with herpes reactivation so antiviral prophylaxis should be considered.

Carfilzomib is a second-generation, irreversible inhibitor of the 20S proteasome and is approved for relapsed or refractory multiple myeloma. As a result of its irreversible inhibition, carfilzomib produces more sustained inhibition of the proteasome. Carfilzomib is a more potent and selective inhibitor of the chymotrypsin-like activity of the proteasome and immunoproteasome and has demonstrated the ability to overcome bortezomib resistance in cell lines. Compared to bortezomib, carfilzomib is associated with a lower incidence of peripheral neuropathy, but serious cardiovascular and renal adverse drug reactions have been reported.

Ixazomib is an oral 20S proteasome inhibitor approved with lenalidomide and dexamethasone for the treatment of patients with multiple myeloma. Common adverse drug reactions are gastrointestinal toxicity, thrombocytopenia, peripheral neuropathy, peripheral edema, and back pain. Ixazomib has a unique administration schedule for an oral agent (given on days 1, 8, and 15 of a 28-day cycle) and should be taken on an empty stomach.

Ras Inhibitors

The Kirsten ras (KRAS) oncogene is the most prevalent genomic driver in NSCLC and activating mutations occur in 25% to 30% of nonsquamous NSCLC tumors.[39] In response to extracellular stimuli, KRAS cycles between active guanosine triphosphate-bound and inactive guanosine diphosphate-bound states. The KRAS G12C mutation is the most frequent KRAS variant and, when present, favors active guanosine triphosphate resulting in increased cell signaling. Sotorasib binds to the switch II region only found on the inactive configuration, locking it in the inactive state and preventing downstream activation.[39] Patients taking sotorasib should be monitored for hepatotoxicity and interstitial lung disease. Common adverse drug reactions include diarrhea, musculoskeletal pain, fatigue, and cough.

Rearranged During Transfection (RET) Inhibitors

RET is a proto-oncogene with downstream signaling pathways of MAPK and PI3K-AKT. Activating mutations are associated with medullary thyroid cancer, and oncogenic kinase fusions have been discovered in NSCLC. Pralsetinib and selpercatinib are both oral RET inhibitors approved for the treatment of the following RET fusion-positive solid tumors: metastatic NSCLC; advanced or metastatic medullary thyroid cancer; and advanced or metastatic thyroid cancer refractory to radioactive iodine.

Although approved for the same indications, pralsetinib and selpercatinib have different off-target effects: pralsetinib inhibits FLT3, JAK1-2, VEGFR, PDGFR, and FGFR whereas selpercatinib inhibits VEGFR and FGFR. Their toxicity profile is reflective of their inhibition of VEGFR. Notably, more hematologic adverse drug reactions have been reported with pralsetinib. Selpercatinib has been associated with concentration-dependent QTc prolongation, which is not common with pralsetinib.

Tropomyosin Receptor Kinase (TRK) Inhibitors

Chromosomal rearrangements involving in-frame fusions of neurotrophic tyrosine receptor kinase (*NTRK*) genes with various partners can result in constitutively activated chimeric TRK fusion proteins that can act as oncogenic drivers. Larotrectinib is an inhibitor of TRK proteins and has received a tissue/site agnostic approval. It is indicated for the treatment of adult and pediatric patients with solid tumors that have an *NTRK*-gene fusion. Adverse drug reactions include fatigue, nausea, dizziness, vomiting, transaminitis, cough, constipation, and diarrhea. Warnings with larotrectinib include neurotoxicity and hepatotoxicity.

Similar to larotrectinib, entrectinib is a TRK inhibitor approved for the treatment of solid tumors with an *NTRK*-gene fusion. Entrectinib also inhibits ROS1 and ALK and is indicated for the treatment of ROS1-positive NSCLC. Patients receiving entrectinib should be monitored for cardiac toxicities (including QTc prolongation), CNS effects, fractures, hepatotoxicity, hyperuricemia, and vision disorders.

VEGFR Multikinase Inhibitors

Most small-molecule kinase inhibitors are promiscuous; significant off-target activity is associated with these agents due to the inhibition of multiple kinases. The oral multikinase inhibitors described in this section all inhibit VEGFR and, thus, angiogenesis. However, their activity and adverse drug reaction profile may differ because of off-target effects. Inhibiting downstream signaling from the VEGFR results in class toxicities, including hypertension, proteinuria, wound healing complications, bleeding, VTE, and gastrointestinal perforations/fistulas. Hypertension must be well-controlled prior to therapy initiation. Additionally, patients with recent serious cardiovascular events (eg, myocardial infarction), hemorrhage, or gastrointestinal perforation/fistula should avoid VEGFR inhibitors. Due to altered wound healing, VEGFR inhibitors should be held before elective surgery and after major surgery until adequate wound healing.

Sorafenib and Sunitinib

First-generation inhibitors, sunitinib and sorafenib, inhibit multiple growth factor receptors (eg, VEGFR2 and PDGFR), cell surface proteins (eg, KIT), and cytokine receptors (eg, FLT3), and, thus, disrupt multiple aberrant intracellular signaling pathways. In addition, sorafenib inhibits Raf, which is part of the MAPK signaling pathway. Sunitinib is approved for GIST, pancreatic neuroendocrine tumors, and renal cell carcinoma; and sorafenib is approved for unresectable hepatocellular carcinoma, advanced renal cell carcinoma, and differentiated thyroid carcinoma refractory to radioactive iodine treatment.

In addition to the traditional VEGFR inhibitor toxicities listed above, sunitinib is uniquely associated with a yellow discoloration of the skin or hair which is related to the yellow color of the active drug. Although this adverse drug reaction is benign, patients who develop a yellowing of the skin must be evaluated for hepatotoxicity which has also been reported with sunitinib.

Axitinib, Pazopanib, and Tivozanib

The next-generation inhibitors axitinib, pazopanib, and tivozanib inhibit VEGFR-1, -2, -3, KIT, and PDGFR. However, axitinib and tivozanib have enhanced potency and selectivity to all VEGFR kinases with minor activity against PDGFR and KIT. All three agents are indicated for the treatment of advanced renal cell carcinoma. Pazopanib has an additional indication for the treatment of patients with advanced soft tissue sarcoma who have received prior chemotherapy.

Cabozantinib

Cabozantinib is a small-molecule inhibitor of numerous receptor kinases, most importantly RET, VEGFR2, and MET. As described above, MET is required for several important processes during embryogenesis (eg, angiogenesis) and leads to abnormal growth and proliferation of several tumors. Medullary thyroid cancers express mutated RET as well as VEGFR2 and MET. Cabozantinib is approved for the treatment of metastatic medullary thyroid cancer, renal cell carcinoma, and hepatocellular carcinoma. Toxicities reported in clinical trials include diarrhea, PPE, electrolyte abnormalities, transaminitis, and stomatitis. Of note, cabozantinib is available as both an oral capsule and tablet, which are not bioequivalent and therefore not interchangeable.

Lenvatinib

Lenvatinib primarily inhibits VEGFR-1, -2, and -3, but it can also inhibit other kinases including FGFR, PDGFR, KIT, and RET. Lenvatinib is approved for the following indications: as a single agent for the treatment of radioactive iodine-refractory differentiated thyroid cancer; as a single agent for the treatment of unresectable hepatocellular carcinoma; in combination with everolimus for the treatment of renal cell carcinoma; and in combination with pembrolizumab for patients with advanced endometrial carcinoma. Common toxicities seen with lenvatinib include fatigue, diarrhea, stomatitis, and PPE.

Regorafenib

Regorafenib is a multikinase inhibitor that blocks the activity of several protein kinases, including those involved in the regulation of tumor angiogenesis (VEGFR-1, -2, and -3), oncogenes and downstream targets (KIT, RET, RAF1, and BRAF), as well as PDGFR and FGFR. Many of these targets are important in gastrointestinal carcinomas, and regorafenib has demonstrated activity in these tumors. FDA-approved indications include colorectal cancer, GIST, and hepatocellular carcinoma. Serious adverse drug reactions reported with regorafenib include hepatotoxicity and reversible posterior leukoencephalopathy syndrome. Common adverse drug reactions with regorafenib include asthenia, mucositis, gastrointestinal toxicities, and PPE. To improve tolerability, a weekly dose-escalation strategy has been proposed.[40] Regorafenib should be given orally with a low-fat evening meal, as the toxicities appear minimized when given at night.

Vandetanib

Vandetanib is a small-molecule inhibitor of RET, VEGFR-2 and -3, and EGFR. It is approved for the treatment of metastatic medullary thyroid cancer. Toxicities observed with vandetanib include diarrhea and rash. Vandetanib can prolong the QTc interval, and cases of Torsades de pointes and sudden death have been reported. Because of this risk, vandetanib is only available through a REMS program where prescribers and pharmacies must be certified through the program before prescribing or dispensing vandetanib.

TARGETED AGENTS: ANTIBODIES

⑦ Biologic therapies are a diverse group of agents that include cytokines, mAbs, and growth factors. Biologics are generally large and complex molecules that are manufactured in a microorganism or other living system. The mAb is the most common biologic therapy available to treat patients with solid tumors and hematologic malignancies.

Biosimilars

Due to the complex process associated with manufacturing biologics, “generic” biologic products are not approved in the same manner as small-molecule pharmaceuticals. Unlike generic small-molecule agents that must demonstrate bioequivalence to a branded product, biosimilars must be “highly similar” to the reference product. Biosimilars must demonstrate that no clinically meaningful differences in safety, purity, and potency exist between it and the reference product. Some biosimilar agents undergo additional evaluation and testing to meet the requirements of an “interchangeable product.” An interchangeable product is expected to produce the same clinical result as the reference product and can generally be substituted without consulting the prescriber.[41] Of note, some institutions have a therapeutic interchange list that permits substitutions of biosimilars based on policies developed by the local Pharmacy and Therapeutics Committee.

Monoclonal Antibodies

A mAb is designed to target a pathway critical for the survival and proliferation of cancer cells resulting in selective destruction of the malignant cells while minimizing toxicities to healthy tissues. The mAb can bind to either the extracellular receptor or its natural ligand and prevent the activation of downstream intracellular signaling. Additionally, some immunotherapies (eg, immune checkpoint inhibitors) are mAbs that target a specific pathway to allow for immune activation.

Each mAb consists of immunoglobulin sequences that are known to recognize a specific antigen or protein on the surface of cells. There are five classes of immunoglobulins, but IgG is the most commonly used therapeutically. Similar to endogenous antibodies, the Fab portion is composed of heavy and light chains that are responsible for binding to antigens, and the constant region determines the effector function of the antibody. The mAb may be naked (unconjugated) or conjugated to a toxin (immunotoxin), chemotherapy agent (antibody-drug conjugate [ADC]), or radioactive particle (radioimmunoconjugate).

In 2017, the standard nomenclature for mAbs was revised. As before, mAbs receive a random prefix, an infix indicating the target, and the suffix “-mab.” However, the prior requirement to include the source (ie, -o-, -u-, -xi-, and -zu- to indicate murine, human, chimeric, and humanized, respectively) has been removed. The nonproprietary name of a mAb consists of a core name (eg, trastuzumab) and a distinguishing suffix composed of four lowercase letters (eg, trastuzumab-dkst). If the product is conjugated, a separate word is added to identify the toxin, chemotherapy, or radioactive particle. For example, the ADC ado-trastuzumab emtansine consists of the mAb trastuzumab plus emtansine which identifies the name of the cytotoxic payload and linker. The prefix “ado” was added to reduce the potential for confusion between the ADC and the unconjugated mAb.

The first mAbs used in humans were murine, but most of the antibodies used today are humanized or human. These agents differ in the amount of foreign component. Hypersensitivity and infusion-related reactions, with or without the development of antiproduct antibodies, are generally greatest with murine antibodies and least with humanized antibodies. The severity of these reactions can range from mild (eg, fever, chills, nausea, and rash) to severe, life-threatening anaphylaxis with cardiopulmonary collapse. Patients with a hypersensitivity or infusion-related reaction may also experience chest or back pain during the infusion. Patients with circulating cancer cells in the bloodstream are at highest risk for more severe reactions. Patients must be monitored closely during infusion. The reactions tend to be more severe with the initial few treatments and subside with subsequent infusions. Some mAbs require premedication, including antihistamines, acetaminophen, or corticosteroids, to minimize hypersensitivity reactions. Recommended infusion rates may be longer for the initial dose, with incremental increases as tolerated. For patients experiencing signs or symptoms of infusion-related reactions, the infusion should be interrupted, and prompt treatment with antihistamines, corticosteroids, and other supportive measures should be initiated. Other adverse drug reactions are typically determined by the selectivity of the target antigen. mAbs against antigens found on normal and cancer cells are expected to have increased toxicity compared with tumor-specific antigens found only on malignant tissues.

Unconjugated mAbs that target antigens on the cell surface of cancer cells may induce death of cancer cells by several mechanisms. These mAbs could directly mediate cell killing through CDC, ADCC, or inhibiting intracellular signaling. CDC occurs when the Fc portion of the antibody activates the complement system, leading to tumor cell lysis. ADCC occurs when effector cells that contain Fc receptors bind to the Fc portion of the antibody and either lyses or phagocytizes the antibody-containing cell. Natural killer cells, monocytes, and macrophages are all capable of mediating ADCC. Finally, antibody binding may result in the transmission of signals that induce apoptosis or programmed cell death in the targeted cell.

Immunoconjugates deliver a payload, typically a chemotherapy agent, toxin, or radioactive particle to a cell targeted by the antibody. After the antibody binds the target antigen, the payload is internalized by the target cell and kills cancer cells through traditional mechanisms of action. In addition to killing the target cell, radioimmunoconjugates are capable of killing antigen-negative cancer cells, sometimes termed the “bystander effect.” Theoretically, immunoconjugates deliver therapy to specific sites of disease while limiting systemic exposure to the chemotherapy, radiation, or toxin. The mAb might also contribute to the observed anticancer effects.

Antibody-Drug Conjugates

ADCs were developed to exploit the selectivity and binding properties of mAbs to deliver cytotoxic chemotherapy directly to the targeted cell. These agents consist of three components: the antibody, the linker, and the cytotoxic payload. To cause cancer cell death, the antibody must first bind to the target antigen, and then the complex must be internalized into the cell through receptor-mediated endocytosis. The antibody-drug complex is then degraded, the cytotoxic payload is released, and cancer cell death occurs. Theoretical benefits of conjugates are a result of the delivery of cytotoxic chemotherapy directly to the target site resulting in decreased toxicity.

Antibodies that Target B-Cell Maturation Antigen

The B-cell maturation antigen, or BCMA, is overexpressed on multiple myeloma cells and is thought to play a role in cell survival. Belantamab mafodotin, an ADC that targets B-cell maturation antigen, is approved for the treatment of multiple myeloma. Monomethyl auristatin phenylalanine is a microtubule-disrupting agent that is attached via a linker to the mAb. Belantamab mafodotin is available through a REMS program to manage the risk of ocular toxicity and it requires registration of patients and providers. Severe vision loss, corneal ulcer, blurred vision, and dry eye have been associated with belantamab mafodotin. Although the mechanism of ocular toxicity is still under investigation, it is theorized that an uptake of the ADC into the corneal epithelial tissue may be the culprit.[42] Other common toxicities include thrombocytopenia and infusion-related reactions.

Antibodies that Target CD19

The CD19 antigen is a cell surface protein expressed on B-cell lymphocytes and B-cell malignancies. Overexpression leads to tumor cell proliferation. Destruction of CD19-expressing malignant cells may be accomplished through a bispecific T-cell engager (eg, blinatumomab) or through CAR T-cell therapy (eg, axicabtagene ciloleucel, brexucabtagene autoleucel, lisocabtagene maraleucel, tisagenlecleucel) which are discussed later in the chapter.

Tafasitamab is a humanized mAb that targets CD19 and mediates ADCC, antibody-dependent cellular phagocytosis, and direct cytotoxicity.[43] It has demonstrated synergistic activity in combination with lenalidomide and is approved for the treatment of relapsed or refractory diffuse large B-cell lymphoma in patients who are not eligible for autologous HSCT. Patients receiving tafasitamab should be monitored for infusion-related reactions, myelosuppression, and infections.

Loncastuximab tesirine is an ADC-targeting CD19, and the cytotoxic payload is an alkylating agent (SG3199). It is approved for the treatment of patients with large B-cell lymphoma. Patients receiving loncastuximab tesirine must be monitored for effusions and edema, myelosuppression, infections, and cutaneous reactions. Photosensitivity reactions have also been reported so patients should be counseled to minimize or avoid exposure to sunlight.

Antibodies That Target CD20

Rituximab

Rituximab is a chimeric antibody directed against the CD20 antigen found on the surface of normal and cancerous B-cells. The Fab domain of rituximab binds to the CD20 antigen on B lymphocytes and the Fc domain recruits immune effector functions to mediate B-cell lysis. The mechanisms of its anticancer effect include CDC and ADCC of malignant B-cells and possibly a direct apoptotic effect.

Rituximab is approved for the treatment of low-grade or follicular, CD20-positive, B-cell NHL in multiple settings and for the treatment of CD20-positive CLL with standard chemotherapy. Rituximab is also indicated for the treatment of a variety of immune-mediated diseases, including rheumatoid arthritis, granulomatosis with polyangiitis, and microscopic polyangiitis. It is administered as an intravenous infusion.

Infusion-related reactions associated with rituximab primarily occur during the first infusion and are components of an infusion-related complex secondary to the amount of circulating B-cells. After the first infusion, the incidence and the severity of these reactions decrease dramatically. Premedication and additional supportive care medications may be required depending on indication. The most common reactions with the infusion-related complex are transient fever, chills, nausea, asthenia, and headache. Additionally, rituximab and other mAbs targeting CD20 may cause HBV reactivation and should not be administered in patients with severe, active infections.

Rituximab is also available in combination with hyaluronidase, which is administered via subcutaneous injection. When mAbs are administered subcutaneously, hyaluronidase is a necessary component because it degrades hyaluronan and allows for a more permeable extracellular matrix providing greater diffusion capacity and bioavailability of the mAb. All patients must receive at least one full dose of a rituximab product by intravenous infusion without experiencing severe adverse drug reactions before starting treatment with rituximab/hyaluronidase. The combination product is approved for follicular lymphoma, diffuse large B-cell lymphoma, and CLL.

Obinutuzumab

Obinutuzumab is a type II humanized anti-CD20 mAb approved for CLL and follicular lymphoma. When compared with the type I anti-CD20 antibodies such as rituximab, type II agents exhibit a different elbow hinge angle and therefore bind CD20 in a different orientation. Furthermore, the Fc portion of obinutuzumab has been glycoengineered to reduce fucosylation resulting in improved receptor affinity and enhanced ADCC potency.[44]

Adverse drug reactions associated with obinutuzumab include infusion-related reactions, myelosuppression, nausea, and diarrhea. HBV reactivation and progressive multifocal leukoencephalopathy have also been reported with obinutuzumab.

Ofatumumab

Ofatumumab is a type I human mAb that also targets the CD20 antigen. Its mechanism of action is similar to that of rituximab, but ofatumumab targets a different epitope than rituximab, has greater affinity for the antigen, and dissociates from the epitope slower than rituximab. Specifically, ofatumumab binds to two regions of the CD20 antigen, the small extracellular loop and the N-terminal region of the large extracellular loop. As a result, anticancer activity has been demonstrated in patients who have progressed on rituximab in a variety of B-cell cancers. Ofatumumab is approved for the treatment of CLL. Adverse drug reactions are similar to rituximab with fewer infusion-related reactions and a higher rate of infectious complications.

Antibodies That Target CD22

CD22 is expressed on over 90% of leukemic blasts in patients with B-cell ALL. Inotuzumab ozogamicin is an ADC-targeting CD22 on B-cells. This agent consists of an IgG4 antibody linked to calicheamicin (an antitumor antibiotic) and is approved for the treatment of relapsed or refractory B-cell precursor ALL in adults. Prescribing information for inotuzumab ozogamicin warns of the risk for increased post-HSCT nonrelapse mortality rate. Potentially severe toxicities include hepatotoxicity, myelosuppression, infusion-related reactions, and QTc prolongation.

Antibodies That Target CD30

Brentuximab vedotin is an ADC that targets the CD30 antigen found on cancer cells. Upon binding to the CD30 antigen, brentuximab vedotin is internalized by endocytosis and the dipeptide bond that links the naked mAb to the chemotherapy monomethylauristatin E (also known as MMAE) is cleaved. Monomethylauristatin E then binds to microtubules and acts as an inhibitor of microtubule polymerization. It may also induce apoptosis by inhibiting NF-κB. Brentuximab vedotin is indicated for Hodgkin lymphoma, anaplastic large cell lymphoma, peripheral T-cell lymphoma, and mycosis fungoides. Infusion-related reactions, peripheral neuropathy, and neutropenia are common toxicities seen with brentuximab vedotin administration; these toxicities are common with other microtubule inhibitors.

Antibodies That Target CD33

Consisting of an IgG4 kappa antibody linked to a calicheamicin derivative, gemtuzumab ozogamicin is an ADC-targeting CD33, which is expressed on leukemic cells in AML. Gemtuzumab ozogamicin has a unique approval history. In 2000, gemtuzumab ozogamicin received an accelerated approval for the treatment of patients with AML but was removed from the market soon thereafter due to lack of benefit and excessive toxicity. However, since then, multiple studies have been completed using a modified dosing scheme resulting in the reapproval of gemtuzumab ozogamicin for the treatment of CD33-positive AML. Warnings associated with the use of this agent include hepatotoxicity (including veno-occlusive disease), infusion-related reactions, and hemorrhage. Other common toxicities are infection, fever, nausea, vomiting, constipation, headache, rash, and mucositis.

Antibodies That Target CD38

Daratumumab is a mAb that inhibits CD38-expressing tumor cells by inducing apoptosis directly through Fc-mediated cross-linking and immune-mediated tumor cell lysis through CDC, ADCC, and antibody-dependent cellular phagocytosis. Myeloid-derived suppressor cells and a subset of regulatory T-cells express CD38. Daratumumab is administered as an intravenous infusion and is also available in combination with hyaluronidase for subcutaneous injection. Both formulations are approved for the treatment of patients with multiple myeloma and are typically given in combination with other anticancer agents.

The most frequently reported adverse drug reactions are infusion-related reactions, fatigue, nausea, back pain, pyrexia, cough, upper respiratory tract infection, and myelosuppression. Premedications (corticosteroid, antipyretic, and an antihistamine) and a postinfusion medication (corticosteroid) are recommended to prevent acute and delayed infusion reactions. Daratumumab interferes with blood bank cross-matching by binding to CD38 on red blood cells possibly resulting in a positive indirect Coombs test. It is therefore recommended that a type and screen be performed prior to treatment initiation. If a blood transfusion is necessary, inform the blood bank that the patient has received daratumumab.

Isatuximab is a mAb-targeting CD38 that is indicated for the treatment of multiple myeloma in combination with dexamethasone and either pomalidomide or carfilzomib. Warnings associated with isatuximab are similar to those with daratumumab including infusion-related reactions and a false-positive indirect Coombs test. Additionally, patients receiving isatuximab are at risk of developing a second primary malignancy, such as skin cancer. In one study, the overall incidence of a second primary malignancy was 3.9% in patients receiving isatuximab, pomalidomide, and dexamethasone versus 0.7% in patients receiving only pomalidomide and dexamethasone.[45]

Daratumumab, isatuximab, and all other mAbs approved for the treatment of multiple myeloma (regardless of target) are associated with a warning for interference with the M-protein assay which is used for the clinical monitoring of patients with multiple myeloma. The interference is related to the assay being unable to distinguish between M-proteins and mAbs.

Antibodies That Target CD52

Alemtuzumab is a recombinant humanized mAb that is directed against CD52. CD52 is expressed on the surface of B and T lymphocytes, natural killer cells, monocytes, and macrophages. Its anticancer activity comes from binding to the CD52 antigen present on leukemic lymphocytes and inducing cell lysis and death. Alemtuzumab is indicated as a single agent for the treatment of B-cell CLL.

Alemtuzumab is associated with severe infusion-related reactions, hematologic toxicity, and opportunistic infections. Hematologic toxicity consisting of severe prolonged neutropenia and thrombocytopenia occurs in most patients. Health professionals should monitor complete blood counts before each dose to determine the need for dose modification. Since CD52 is expressed on lymphocytes, alemtuzumab can induce profound lymphopenia including a decrease in CD4 and CD8 counts. Patients should receive prophylaxis for *Pneumocystis jirovecii* pneumonia and herpes virus, which should be continued for a minimum of 2 months after completing alemtuzumab therapy or until recovery of CD4 counts. Alemtuzumab is only available through a restricted distribution program that allows access for patients deemed appropriate for treatment.

Antibodies That Target CD79B

While CD79B is present on the surface of most malignant B-cells, its expression on mature B-cells is restricted, thus making it an attractive target.[46]

Polatuzumab vedotin is an ADC consisting of monomethylauristatin E conjugated to an anti-CD79B mAb. It is given in combination with bendamustine and rituximab for the treatment of diffuse large B-cell lymphoma. Toxicities include peripheral neuropathy, infusion-related reactions requiring premedications, myelosuppression, infections, multifocal leukoencephalopathy, TLS, and hepatotoxicity.

Antibodies That Target Chemokine Receptor

Mogamulizumab is a recombinant humanized IgG1 kappa mAb that targets CC chemokine receptor 4–expressing cells. CC chemokine receptors are a subfamily of chemokine receptors that possess four cysteine residues; chemokines are chemoattractants that facilitate the migration of cells. CC chemokine receptor 4 is involved in the trafficking of lymphocytes to various organs. Mogamulizumab is indicated for relapsed or refractory mycosis fungoides or Sézary syndrome. The most common adverse drug reactions are rash, infusion-related reactions, fatigue, diarrhea, musculoskeletal pain, and upper respiratory tract infection.

Antibodies That Target GD2

Glycolipid GD2 is expressed primarily on the cell surface of neuroblastoma cells and on normal tissues, including neurons and peripheral sensory nerve fibers.[47] The function of the GD2 carbohydrate antigen is not completely understood, but it is thought to play a role in the attachment of tumor cells to extracellular matrix proteins.[47] Dinutuximab is a chimeric mAb that binds GD2, thereby inducing cell lysis through ADCC and CDC. This activity is thought to be enhanced when dinutuximab is given with granulocyte-macrophage colony-stimulating factor (GM-CSF) and interleukin-2. Dinutuximab is approved to be given with GM-CSF, interleukin-2, and 13-cis-retinoic acid for the treatment of pediatric patients with high-risk neuroblastoma. Serious toxicities associated with dinutuximab include infusion-related reactions and neurotoxicities. Patients should be monitored for infections, hypokalemia, hypotension, and capillary leak syndrome. Severe neuropathic pain occurs in most patients and intravenous opioids are required prior to, during, and immediately following administration.

Similar to dinutuximab, naxitamab binds to cell surface GD2 and induces ADCC and CDC. Naxitamab is indicated in combination with GM-CSF for the treatment of pediatric and adult patients with high-risk neuroblastoma. Serious toxicities include infusion-related reactions, neurotoxicity, and hypertension. To manage severe neuropathic pain, patients should receive a 12-day course of a neuropathic pain medication (eg, gabapentin) starting 4 days before initiation in addition to opioids before the start of the infusion.

Antibodies That Target Nectin-4

Using the microtubule-disrupting agent monomethylauristatin E as its payload, enfortumab vedotin is an ADC-targeting nectin-4 that is approved for the treatment of urothelial carcinoma. Nectin-4 is an adhesion protein on cell surfaces that is highly expressed in urothelial cancer and also reported in breast, lung, and pancreatic cancer. Serious adverse drug reactions associated with enfortumab vedotin include skin reactions, peripheral neuropathy, hyperglycemia, and ocular disorders. Patients, particularly those with diabetes mellitus, should monitor blood glucose levels closely, and enfortumab vedotin should be held if blood glucose is greater than 250 mg/dL (13.9 mmol/L). Patients should be monitored for vision changes, and prophylactic artificial tears may be considered for dry eyes.

Antibodies That Target EGFR

Cetuximab

Cetuximab is a chimeric mAb that binds specifically to the extracellular domain of EGFR on both normal and cancer cells, and competitively inhibits the binding of epidermal growth factor and other ligands, such as transforming growth factor-α. Binding of cetuximab to the EGFR inhibits cell growth, induces apoptosis, and inhibits VEGF production. Cetuximab is indicated for the treatment of metastatic KRAS wild-type (ie, without mutation) colorectal cancer and for squamous cell head-and-neck cancer. Acneiform rash and skin reactions occur in most patients receiving cetuximab, as observed with other agents that inhibit EGFR. Multiple follicular or pustular lesions generally appear within the first 2 weeks of therapy and usually resolve after cessation of treatment. Resolution can be slow, continuing beyond 28 days in nearly half of cases. In patients who develop a severe rash, dose modifications may be necessary. Interestingly, a trend for improved responses with increasing severity of skin reactions has been suggested but additional research is required to confirm this association.[29]

Additionally, patients receiving cetuximab should be monitored for other serious adverse drug reactions including infusion-related reactions and electrolyte abnormalities. Hypomagnesemia may be severe and can occur within days or months after treatment. Cardiopulmonary arrest and sudden death have also been reported.

Panitumumab

Panitumumab, the first human mAb approved to treat cancer, is an IgG2 antibody that binds to the cell surface EGFR. It is approved to treat RAS wild-type metastatic colon cancer. Adverse drug reactions are similar to cetuximab, although severe infusion-related reactions appear to be less common because panitumumab does not have a murine component.

Both cetuximab and panitumumab are more effective in patients with tumors that are RAS wild-type compared to tumors that are RAS mutation-positive. Therefore, patients with metastatic colorectal cancer should not receive anti-EGFR antibody therapy if a RAS mutation is detected. Genetic testing of colorectal cancers is discussed in further detail in Chapter 153, “Colorectal Cancer.”

Necitumumab

Necitumumab is a next-generation mAb that binds to the human EGFR and blocks the binding of EGFR to its ligands. It is approved for the treatment of patients with metastatic *squamous* NSCLC in combination with gemcitabine and cisplatin. Serious and clinically significant adverse drug reactions include cardiopulmonary arrest, hypomagnesemia, thromboembolic events, dermatologic toxicities, and infusion reactions. Since increased toxicity and mortality was observed when necitumumab was given with pemetrexed and cisplatin for the treatment of nonsquamous NSCLC, patients with metastatic nonsquamous NSCLC should not receive necitumumab.

Antibodies That Target EGFR and MET

Amivantamab is a bispecific antibody that binds both EGFR and MET. It is approved for the treatment of patients with NSCLC that harbors an EGFR exon 20 insertion mutation. These mutations are associated with de novo EGFR inhibitor resistance and a poor patient prognosis.[48] Due to the high incidence of amivantamab infusion-related reactions, the prescribing information recommends premedications and peripheral administration of the first two infusions. Other serious adverse drug reactions include interstitial lung disease, dermatologic toxicities, and ocular toxicities.

Antibodies That Target HER2

HER2-Targeting mAbs

Trastuzumab is a humanized mAb that selectively binds to HER2. HER2 is overexpressed in about 33% of breast cancers, in about 22% of gastroesophageal junction and gastric cancers, and to varying degrees in other malignancies. Trastuzumab inhibits cell-cycle progression by decreasing cells entering the S phase of the cell cycle, which leads to downregulation of HER2 receptors on cancer cells and decreased cell proliferation. Trastuzumab also leads to ADCC and CDC and directly induces apoptosis in cells overexpressing HER2. In addition, synergy between trastuzumab and chemotherapy has been demonstrated, resulting in trastuzumab often being used in combination regimens. Trastuzumab is administered via intravenous infusion and is approved for the treatment of HER2-positive breast cancer and metastatic gastric or gastroesophageal junction adenocarcinoma. The tumor should overexpress HER2 as measured by diagnostic tests that can quantify gene amplification or protein expression. Additionally, a trastuzumab and hyaluronidase subcutaneous injection formulation has been approved for the treatment of HER2-positive breast cancer.

The most serious adverse drug reactions associated with trastuzumab include cardiomyopathy, hypersensitivity reactions, and increased myelosuppression. An evaluation of cardiac function should be performed before administration and extreme caution should be exercised in patients with pre-existing cardiac dysfunction and in those who have received prior anthracyclines. In patients who develop a clinically significant decrease in LVEF (defined as greater than 16% decrease in ejection fraction from pretreatment levels or an ejection fraction below normal limits and greater than 10% decrease from baseline), discontinuation of therapy should be considered. Myelosuppression is infrequent with trastuzumab alone, but the incidence of neutropenia and febrile neutropenia is higher when trastuzumab is given with myelosuppressive chemotherapy.

Pertuzumab is a humanized mAb that targets the HER2 receptor. It is synergistic with trastuzumab and is effective in tumors that have developed resistance to trastuzumab. Pertuzumab binds to the extracellular domain II of HER2, a site distinct from trastuzumab, and inhibits ligand-dependent HER2–HER3 dimerization, which subsequently decreases tumor proliferation and resistance pathways. Dual targeting of the HER2 receptor allows for increased efficacy against variant forms of the HER2 receptor, including truncated HER2 receptors. Similar to trastuzumab, it appears to induce ADCC in cancer cells. Pertuzumab is approved to treat HER2-overexpressed breast cancer in combination with trastuzumab and chemotherapy. Warnings and precautions are similar to those of trastuzumab, including a boxed warning for cardiotoxicity.

Because pertuzumab and trastuzumab are often administered as part of the same regimen in clinical practice, a subcutaneous formulation of these agents in combination with hyaluronidase was developed for the treatment of breast cancer. Warnings associated with this agent include cardiomyopathy, pulmonary toxicity, exacerbation of chemotherapy-induced neutropenia, and administration-related reactions.

Margetuximab, another HER mAb, binds to the same extracellular domain of HER2 as trastuzumab, but has a modified Fc region. The modified Fc is thought to allow for increased binding to the activating receptor and decreased binding to the inhibitory receptor, thus leading to greater ADCC compared to trastuzumab.[49] Margetuximab is approved for the treatment of HER2-positive metastatic breast cancer in combination with chemotherapy in patients who have received two or more prior anti-HER2 regimens. Similar to other agents in this class, the margetuximab product labeling contains a warning for left ventricular dysfunction.

HER2-Targeting ADCs

Ado-trastuzumab emtansine (sometimes referred to as T-DM1) is indicated for the treatment of HER2-positive breast cancer, whereas fam-trastuzumab deruxtecan is approved for the treatment of patients with HER2-positive breast cancer and gastric cancer. Ado-trastuzumab emtansine is an ADC that consists of the humanized anti-HER2 mAb trastuzumab covalently linked to the microtubule inhibitory drug derivative of maytansine 1. The adverse drug reactions associated with ado-trastuzumab emtansine are similar to those reported with trastuzumab and microtubule inhibitors.

Fam-trastuzumab deruxtecan is an ADC that consists of an anti-HER2 mAb covalently linked to DX-8951 derivative, a topoisomerase I inhibitor. Warnings on the product labeling include pneumonitis, neutropenia, and left ventricular dysfunction. Unlike most ADCs, nausea and vomiting are common with fam-trastuzumab deruxtecan, and it is associated with a moderate emetic risk. It is important to note that ado-trastuzumab emtansine, fam-trastuzumab deruxtecan, and trastuzumab are not interchangeable and should not be substituted for one another.

Monoclonal Antibodies That Target Signaling Lymphocytic Activation Molecule Family 7 (SLAMF7)

Elotuzumab is an IgG mAb directed against SLAMF7. SLAMF7 is expressed on multiple myeloma cells, natural killer cells, and other immune cells. The antitumor effects of elotuzumab are a result of ADCC and through blocking multiple myeloma and stromal cell interaction but it is not thought to induce CDC.[50] Elotuzumab is approved in combination with lenalidomide and dexamethasone for the treatment of patients with multiple myeloma. The most common adverse drug reactions reported include fatigue, diarrhea, constipation, pyrexia, peripheral neuropathy, decreased appetite, cough, and respiratory infections. Patients should also be monitored for infusion-related reactions, infections, second primary malignancies, and hepatotoxicity.

Antibodies That Target Trophoblast Cell-Surface Antigen 2 (TROP2)

Sacituzumab govitecan is an ADC-targeting TROP2, which is a transmembrane calcium signal transducer overexpressed in many epithelial cancers. The cytotoxic payload of sacituzumab govitecan is SN-38 which, as described above, is the active metabolite of the topoisomerase I inhibitor irinotecan. Therefore, precautions and adverse drug reactions are similar between these agents. Boxed warnings for sacituzumab govitecan include neutropenia and diarrhea. The management strategy for diarrhea is similar to that of irinotecan: atropine is used for acute diarrhea, whereas loperamide is the best option for delayed diarrhea. Patients homozygous for the UGT1A1*28 allele are at increased risk of neutropenia, febrile neutropenia, and anemia. Sacituzumab govitecan is approved for the treatment of triple negative breast cancer and urothelial carcinoma.

Antibodies That Target VEGF

Bevacizumab

Bevacizumab is a humanized mAb directed against circulating VEGF. It binds to all biologically active circulating isoforms of VEGF and prevents the activation and promotion of angiogenesis. Bevacizumab is approved for the treatment of patients with multiple types of solid tumors including the following: cervical cancer; colorectal cancer; glioblastoma; nonsquamous NSCLC; ovarian, fallopian tube, or primary peritoneal cancer; and renal cell carcinoma. A bevacizumab biosimilar, bevacizumab-awwb, was the first biosimilar approved for the treatment of cancer.

Several serious adverse drug reactions have been associated with bevacizumab, including hypertension, bleeding, and thrombotic events. Hypertension is more common in patients with a history of uncontrolled blood pressure, and it responds to oral antihypertensive medications. Although the most common bleeding episodes are transient epistaxis, fatal CNS and gastrointestinal hemorrhages have been reported. The product labeling includes warnings regarding the risk of gastrointestinal perforation, wound dehiscence, and hemorrhage. Bevacizumab is not recommended for use within 28 days of major surgery and patients should be instructed to report abdominal pain (an initial sign of gastrointestinal hemorrhage) to their health professionals immediately. Paradoxically, bevacizumab also has been associated with thrombotic events, including deep vein thrombosis, pulmonary embolism, and myocardial infarction, especially in elderly patients with a history of cardiac events. Another potentially serious adverse drug reaction associated with bevacizumab is proteinuria/nephrotic syndrome, and patients should be monitored for the development or worsening of proteinuria with serial urine dipsticks.

Ramucirumab

Ramucirumab is a human mAb that binds to VEGFR2 resulting in the inhibition of ligand-induced proliferation. While bevacizumab binds the circulating ligand (ie, VEGF), ramucirumab inhibits angiogenesis through the specific blockade of VEGFR2. Ramucirumab is approved for the treatment of advanced gastric or gastroesophageal junction adenocarcinoma as a single agent or with paclitaxel. Other indications include the following: treatment of metastatic NSCLC in combination with erlotinib or docetaxel; treatment of hepatocellular carcinoma in patients who have an AFP of ≥ 400 ng/mL (mcg/L) following treatment with sorafenib; and for the treatment of metastatic colorectal cancer in the second-line setting. When administered as a single agent, the most common toxicities associated with ramucirumab are hypertension and diarrhea. Patients should also be monitored for thromboembolic events, hypertension, proteinuria, and thyroid dysfunction.

Bispecific T-Cell Engagers

Blinatumomab is a bispecific T-cell engaging antibody directed against a B-lymphocyte-specific molecule CD19. Through the formation of a synapse, blinatumomab serves as a linker between CD19 on malignant B-cells and CD3 on T-cells, thereby potentiating T-cell–induced cytotoxic cell killing. Blinatumomab is indicated for the treatment of CD19-positive B-cell precursor ALL.

Due to its short half-life (~2 hours) and mechanism of action, blinatumomab is administered as a continuous intravenous infusion over 28 days. In addition to possible decreased efficacy, early trials that utilized shorter infusion durations also reported a higher rate of neurologic toxicities and cytokine release syndrome (CRS). Patients receiving blinatumomab are usually hospitalized for initiation of cycles 1 and 2 to monitor for infusion-related reactions. Patients should also be monitored for CRS, neurological toxicities, and infections. Other common adverse drug reactions include fever, headache, peripheral edema, and rash.

Fusion Proteins

Moxetumomab pasudotox is a CD-22-directed cytotoxin that is composed of a recombinant murine immunoglobulin variable domain fused to a truncated form of *Pseudomonas* exotoxin. It is approved for the treatment of relapsed or refractory hairy cell leukemia. The most common adverse drug reactions include infusion-related reactions, edema, nausea, headache, pyrexia, constipation, anemia, and diarrhea. Most patients develop anti-moxetumomab binding and neutralizing antibodies.

Ziv-aflibercept is a soluble recombinant fusion protein that was designed to block multiple signals that stimulate the angiogenic process. It was developed by fusing sections of the VEGFR1 and VEGFR2 immunoglobulin domains to the Fc portion of human IgG1. Ziv-aflibercept blocks VEGFA, VEGFB, and phosphatidylinositol-glycan biosynthesis class F by "trapping" the ligands before they get to the native transmembrane receptors and thus decreasing proangiogenic signaling and tumor growth. It is approved with chemotherapy for resistant or progressive metastatic colorectal cancer and has toxicities similar to other anti-VEGF therapies.

IMMUNOTHERAPY

Immune Checkpoint Inhibitors

8 As discussed earlier in the chapter, immune checkpoint inhibitors (including PD-1, PD-L1, and CTLA-4 inhibitors) reverse immune down-regulation,

thereby unleashing T-cells to eliminate malignant cells. PD-L1 is overexpressed on multiple types of tumors, and it has been suggested that PD-L1 expression is associated with increased tumor aggressiveness. Unlike cytotoxic chemotherapy, which can elicit cell death immediately after administration, immune checkpoint inhibitors may have a slower onset based on their inherent mechanism of action. Furthermore, durable responses are more common with checkpoint inhibitors compared to cytotoxic chemotherapy as immune activation against the tumor may continue months after administration. Given their potential to activate the immune system, immune-related adverse events (irAEs) may occur. Immune checkpoint inhibitors should be avoided in patients with underlying autoimmune conditions or a history of transplant—see more details in Chapter 150 "Supportive Care."

CTLA-4 Inhibitor

Ipilimumab is a human mAb that blocks CTLA-4 and was the first FDA-approved immune checkpoint inhibitor. CTLA-4 acts as a negative regulator of T-cell function, decreasing the ability of the immune system to mount an antitumor response. By binding to CTLA-4, ipilimumab allows for enhanced T-cell stimulation, proliferation, and antitumor activity. Based on its ability to produce an enhanced immune response, ipilimumab has been associated with several severe and fatal irAEs including enterocolitis, hepatitis, dermatitis, neuropathies, and endocrinopathies. Infusion-related reactions may occur. Ipilimumab is often administered in combination with nivolumab and is indicated for the treatment of MSI-H or dMMR colorectal cancer, melanoma, NSCLC, mesothelioma, hepatocellular carcinoma, and renal cell carcinoma.

PD-1 Inhibitors

As described earlier in the chapter, PD-1 inhibitors bind to the PD-1 receptor and block the interaction of its ligand resulting in the restoration of T-cell activity. The toxicity profile of all four medications in this class is similar and includes fatigue and irAEs, Common irAEs include dermatologic conditions and endocrine dysfunction. Patients should also be monitored for potentially fatal irAEs including colitis, pneumonitis, nephritis, hepatitis, myocarditis, and neurologic events.

Cemiplimab is a recombinant human IgG4 mAb approved for the treatment of advanced cutaneous squamous cell carcinoma, basal cell carcinoma, and NSCLC. Dostarlimab is a humanized IgG4 mAb approved for the treatment of dMMR recurrent or advanced endometrial cancer.

Nivolumab and pembrolizumab are IgG4 mAbs approved for Hodgkin lymphoma and for the treatment of numerous solid tumors. Both agents were originally studied in patients with metastatic cancer, but their use is now expanding to earlier in the disease course (eg, adjuvant setting). Depending on the indication, these agents may be given alone or in combination with chemotherapy or targeted therapy. Additionally, nivolumab is approved to be given in combination with ipilimumab, as described above.

Pembrolizumab received the FDA's first tissue/site agnostic approval for the treatment of MSI-H or dMMR solid tumors. It is also approved for tumor mutational burden-high cancer (≥ 10 mutations/megabase) in patients who have progressed following prior treatment and have no satisfactory alternate options. Tumor mutational burden is a measure of somatic mutations in a tumor and may help identify patients that may benefit from immunotherapy.[51]

PD-L1 Inhibitors

Unlike the PD-1 inhibitors which bind to the receptor, PD-L1 inhibitors bind to the associated ligand resulting in immune activation. Since PD-1 and PD-L1 inhibitors target the same pathway, adverse drug reactions and monitoring are the same.

Atezolizumab is an IgG1 mAb indicated for the treatment of SCLC, triple-negative breast cancer, NSCLC, hepatocellular carcinoma, melanoma, and urothelial carcinoma. Durvalumab, a human IgG1 mAb is approved for patients with NSCLC and SCLC. Avelumab is a human IgG1 mAb approved for the treatment of Merkel cell carcinoma, urothelial carcinoma, and in combination with axitinib for renal cell carcinoma.

Unlike the other PD-L1 inhibitors, infusion-related reactions are common with avelumab, and premedications are required prior to the first four infusions at minimum. The development of antidrug antibodies has been shown to reduce avelumab exposure, and exploratory analyses suggest that the development of these antidrug antibodies may reduce the effectiveness in some populations. The development of antidrug antibodies does not appear to affect the incidence or severity of adverse drug reactions.

Cytokines

Interleukin-2 (aldesleukin)

Interleukin-2 is a cytokine produced by recombinant DNA technology that promotes B- and T-cell proliferation and differentiation and initiates a cytokine cascade with multiple interacting immunologic effects. The interleukin-2 receptor is expressed in increased amounts on activated T-cells and mediates most of the effects of aldesleukin. Anticancer activity depends on proliferation of cytotoxic immune cells that can recognize and destroy cancer cells without damaging normal cells. Some of these cytotoxic cells are natural killer cells, lymphokine-activated killer cells, and tumor-infiltrating lymphocytes. Aldesleukin is approved for the treatment of metastatic renal cell carcinoma and melanoma.

Aldesleukin is a toxic therapy that requires vigorous supportive care under the supervision of experienced healthcare professionals. The most common dose-limiting toxicities are hypotension, fluid retention, and renal dysfunction. Aldesleukin decreases peripheral vascular resistance, producing peripheral vasodilation, tachycardia, and hypotension. A characteristic vascular or capillary leak syndrome produces fluid retention, which in turn can cause respiratory compromise. These toxicities require administration of vasopressors in most patients, judicious use of fluid support and diuretics, and supplemental oxygen. Patients with underlying cardiovascular or renal abnormalities are more susceptible to these toxicities, making careful patient selection important. Most patients treated with aldesleukin experience thrombocytopenia, anemia, eosinophilia, reversible cholestasis, and skin erythema with burning and pruritus; some patients have neuropsychiatric changes, hypothyroidism, and bacterial infections. In general, the toxicities from aldesleukin reverse quickly after therapy is stopped and can be managed or prevented by careful monitoring and supportive care.

Therapeutic Vaccines

Sipuleucel-T was the first therapeutic vaccine approved by the FDA. It is classified as an autologous cellular immunotherapy and is indicated for the treatment of asymptomatic or minimally symptomatic metastatic castrate-resistant prostate cancer. Through leukapheresis, a patient's dendritic cells are collected and isolated, then cultured ex-vivo. The fusion protein is composed of prostate acid phosphatase, or PAP, and GM-CSF. Prostate acid phosphatase is selectively expressed on prostatic tissues and GM-CSF is included to enhance the immune response. Antigen-presenting cells take up this antigen and are then reinfused into the donor patient to stimulate a T-cell response.

Treatment with sipuleucel-T consists of three infusions separated by approximately 2 weeks. Due to the leukapheresis, ex-vivo cell manipulation, and reinfusion, treatment with sipuleucel-T can be logistically challenging. Premedication consisting of acetaminophen and an antihistamine should be given prior to each infusion to decrease the risk of an infusion-related reaction. Common toxicities include chills, fatigue, back pain, nausea, joint ache, and headache.

Talimogene laherparepvec is an oncolytic viral therapy based on a modified herpes simplex virus type 1. Talimogene laherparepvec is modified through the deletion of two herpes simplex virus genes, ICP34.5 and ICP47, and is designed to lyse tumor cells and promote antitumor immunity. It is indicated for the local treatment of unresectable cutaneous, subcutaneous, and nodal lesions in patients with melanoma recurrent after initial surgery and is injected directly into the lesion. The most common toxicities are fatigue, chills, pyrexia, nausea, influenza-like illness, and injection site pain. Pyrexia, chills, and influenza-like illness can occur any time during treatment but are more frequent during the first 3 months. Cellulitis is the most commonly reported serious adverse drug reaction.

CAR T-Cell Therapies

CAR T-cell therapies were the first FDA-approved genetically modified autologous T-cell immunotherapies and are also known as adoptive T-cell therapies. Peripheral blood mononuclear cells are harvested from a patient via apheresis. The T-cells are then reprogrammed with a transgene encoding a CAR, which consists of a binding domain and signaling domains. Following lymphodepletion with a conditioning regimen (often fludarabine and cyclophosphamide), the CAR T-cells are then reinfused into the patient.

The design of CAR T-cells has evolved over the years primarily to improve the signaling capability. Four anti-CD19 CARs are currently FDA-approved: axicabtagene ciloleucel (second-generation agent) for the treatment of follicular lymphoma and large B-cell lymphoma; brexucabtagene autoleucel (second-generation agent) for the treatment of mantle cell lymphoma; tisagenlecleucel (second-generation agent) for the treatment of ALL and diffuse large B-cell lymphoma; and lisocabtagene maraleucel (third-generation agent) for the treatment of large B-cell lymphoma. Binding the CD19-expressing cell activates downstream signaling through the costimulatory signaling domains, resulting in cytokine and chemokine secretion and ultimate destruction of the B-cell. Although all four agents are similar in mechanism, they differ in their costimulatory signaling domains. Axicabtagene ciloleucel and brexucabtagene autoleucel both include a CD28 and CD3-zeta signaling domain, whereas tisagenlecleucel contains a 4-1BB and CD3-zeta domain. Lisocabtagene maraleucel is considered a next-generation CAR T-cell because it contains multiple costimulatory domains, including CD28 and

4-1BB in addition to CD3-zeta.

Additionally, idecabtagene vicleucel, a second-generation CAR therapy targeting B-cell maturation antigen, is approved for the treatment of relapsed or refractory multiple myeloma. Similar to tisagenlecleucel, the idecabtagene vicleucel CAR construct contains signaling domains 4-1BB and CD3-zeta. After binding to the B-cell maturation antigen, the signaling domains will activate cytokine and chemokine secretion, resulting in destruction of the targeted cell.

Toxicities associated with CAR T-cell therapies can be severe and life-threatening. As a result, a REMS program has been implemented which, among other requirements, mandates hospitals and clinics be certified before administering these agents.

Cytokine-associated toxicities are common and include CRS, which manifests with hypotension, tachycardia, fever, and hypoxia. Organ dysfunction may also be present. The typical time to onset of CRS is 2 to 3 days and the usual duration is 7 to 8 days.[52] Immune effector cell-associated neurotoxicity syndrome, or ICANS, is the terminology used for neurotoxicities associated with CAR T-cell treatment. CAR T-cell-related neurotoxicities can be fatal or life-threatening. The typical time to onset is 4 to 10 days after treatment, and symptoms last approximately 14 to 17 days.[52] Common neurotoxicities include encephalopathy, headache, tremor, dizziness, and aphasia, but serious events, such as seizures and cerebral edema, have also been reported. See Chapter 150 “Supportive Care“ for management of CRS and ICANS.

RESPONSE CRITERIA

The response to anticancer agents and other treatment modalities could be described as a cure; complete response, or CR; partial response, or PR; stable disease, or SD; or progression. A cure implies that the patient is entirely free of disease and has the same life expectancy as a cancer-free individual. Because of our inability to detect small numbers of cancer cells, we can never be absolutely certain that an individual patient is cured. Cancers that are curable with treatment are characterized by a stable plateau in the survival curve where the risk of relapse is very low. For most curable cancers, the survival curve has plateaued by about 5 years. Therefore, patients with a curable cancer who are alive 5 years from the time of diagnosis without disease recurrence are often considered “cured,” but patients with some malignancies, such as breast cancer and melanoma, are still at significant risk for relapse after 5 years.

Response Criteria for Solid Tumors

In an attempt to simplify and unify response definitions in clinical practice, clinical trials, and published reports, the response evaluation criteria in solid tumors (RECIST) criteria were developed in 2000 and revised in 2009 (RECIST 1.1).[53] At baseline, overall tumor burden and measurable disease is assessed. Target lesions are identified and measured at baseline and are later re-evaluated to determine objective tumor response. Nontarget lesions are also assessed. A CR means disappearance of all target lesions and any pathological lymph nodes must be reduced in short axis to less than 10 mm. A PR is defined as a 30% or greater decrease in the sum of diameters of target lesions from baseline. Overall, objective response rates for a given treatment are calculated by adding the CR and PR rates. Progressive disease is defined as a 20% or greater increase in the sum of diameters of target lesions when compared to the smallest sum since treatment initiation. The development of one or more new lesions while receiving treatment is also considered progressive disease. A patient whose tumor size neither grows nor shrinks by the above criteria is termed to have stable disease. Some patients may experience subjective improvement in cancer-related symptoms without a defined response. Although clinically important, this does not indicate an objective response. RECIST 1.1 is the most widely accepted criteria for the assessment of tumor response in solid tumors but it does not come without shortcomings. The modified RECIST, or mRECIST, assessment may be more accurate for the evaluation of tumor burden in some cancers.[54]

Furthermore, the emergence of immunotherapy in oncology has led to the need for revised response criteria that accounts for the mechanism of immunotherapeutic agents. RECIST neglects to take into account pseudoprogression (ie, “flare”) associated with these agents, which may inadvertently result in the premature discontinuation of an effective therapy. Pseudoprogression refers to apparent tumor growth on imaging, resulting from an immunotherapy treatment-related effect rather than malignant cell proliferation. The apparent progression is thought to be a result of immune infiltrates and is followed by tumor regression. Immune-related response criteria, or irRC, and immune-related RECIST, or irRECIST, have been proposed to overcome the challenges of RECIST 1.1 with immunotherapy.[55,56]

Response Criteria for Hematologic Malignancies

The response definitions described above are applicable to solid tumors, but leukemias and multiple myeloma are not characterized by discrete, measurable masses. Responses in these cancers are measured by elimination of abnormal cells (eg, return to normal hematology parameters and normal bone marrow in leukemia), return of tumor markers to normal levels (eg, normal serum protein electrophoresis in multiple myeloma), or improved function of affected organs (eg, improved renal function after obstructive uropathy). Cytogenetic markers and molecular techniques have an increasingly important role in determining whether all cancer has been truly eliminated. For example, in CML, the Ph can be detected by polymerase chain reaction techniques even when no leukemia is evident in the bone marrow or bloodstream. Patients without evidence of the Ph are classified as having a complete cytogenetic response. Measuring cytogenetic responses is increasingly common in patients with known cytogenetic abnormalities, and the absence of a complete cytogenetic response may be predictive of disease relapse. Minimal residual disease (MRD) is a prognostic factor used to guide treatment in ALL and AML. Data regarding MRD is still emerging, but it is now recommended that MRD be monitored in patients with AML as MRD positivity is associated with higher relapse rates and shorter survival.[57]

FACTORS AFFECTING TREATMENT RESPONSE

⑨ Factors affecting response include tumor burden, cancer cell heterogeneity, drug resistance, dose intensity, and patient-specific factors, such as pharmacogenomics. The significance of tumor burden was discussed earlier in the chapter. Tumors consist of a heterogeneous population of cells. Because of the genetic instability of cancer cells compared with normal cells, genetic alterations commonly occur during cell division. Large tumors have therefore undergone many cell divisions and express multiple genetic alterations, resulting in genetically varied populations. In 1979, Goldie and Coldman proposed that these cytogenetic changes were not completely random and were highly associated with the ability of tumors to develop drug resistance. The probability of developing resistant cell populations increases as tumor size increases. It is believed that a small percentage of resistant cancer cells may survive initial therapy. Resistant populations later proliferate and eventually become the dominant population, which could explain the common pattern of an initial response to therapy followed by progressive tumor regrowth despite continuing the same treatment.

Drug Resistance

Drug resistance may be either acquired or inherited. Mechanisms of drug resistance include altered drug transport systems, metabolism, and target enzymes; ability to repair drug-induced damage; and insensitivity to drug-induced apoptosis.[2] For example, multidrug resistance has been observed with natural chemotherapies (eg, anthracyclines, vinca alkaloids, epipodophyllotoxins, taxanes), and it occurs when some cancer cells are exposed to increasing concentrations of a specific chemotherapy. Surprisingly, these same cells also become resistant to other structurally unrelated chemotherapies and are therefore considered multidrug resistant. The resistant cancer cells may overexpress the drug transporter P-gp, which enhances the export of these chemotherapies. Other potential mechanisms of drug resistance include inactivation of chemotherapy by glutathione metabolism, upregulation of drug targets, alternative intracellular signaling pathways, and decreased apoptosis. The last mechanism can be mediated by overexpression of BCL-2 or loss of TP53, as discussed earlier in the chapter.

Dose Intensity

The relationship between dose and response has been extensively explored for chemotherapy agents, because dose is believed to be a critical factor in determining response for many cancers. Dose intensity is defined as the dose delivered to the patient over a specified period of time. The three main variables that determine delivered dose intensity are the dose per course, the interval between doses, and the total cumulative dose. Dose density refers to shortening of the usual interval between doses (eg, every 2 weeks instead of every 3 weeks) and is designed to maximize the effects of therapy on tumor growth kinetics. This strategy has been extensively studied in breast cancer. The delivery of optimal dose intensity is often compromised by the toxicities of the anticancer agent. Treatment cycles are commonly delayed because of inadequate recovery from toxicity, especially myelosuppression. Subsequent doses of the anticancer agents are often reduced to prevent or minimize the severity of these toxicities. The impact on patient outcome has been proven in studies showing reduced rates of response and survival in individuals receiving less-than-optimal doses. Understanding the pathophysiology of toxicities has led to the development of more effective agents to prevent and manage these toxicities. The development of chemoprotective agents has facilitated application of dose-intensity principles. For example, CSFs minimize neutropenia and permit delivery of dose-intensive or dose-dense regimens that are myelosuppressive. The concept of dose intensity is particularly important in the setting of high-dose chemotherapy with autologous hematopoietic stem cell support. Although lethal myelosuppression is avoided through HSCT, other severe end-organ toxicities emerge as doses of the anticancer agents are increased.

Molecular Biomarkers

A molecular biomarker is a molecular characteristic of the tumor that influences prognosis or predicts response to a specific therapy. Many of these molecular biomarkers are somatic mutations that contribute to the development of the cancer. Prognostic biomarkers inform the risk of clinical outcomes such as disease progression or recurrence. Numerous tests are currently available that measure tumor gene expression and may provide information on a patient's risk of recurrence. For example, the Oncotype Dx® Breast Cancer Assay measures 21 genes associated with breast cancer recurrence and chemotherapy benefit in select patients with breast cancer. A predictive biomarker predicts response to a specific therapeutic intervention. For example, EGFR and ALK mutations predict response to EGFR and ALK inhibitors in NSCLC. Similarly, HER2 overexpression predicts response to trastuzumab in breast cancer. Molecular testing of cancer at the time of diagnosis allows for personalized therapy with targeted agents.

Patient-Specific Factors

Patient-specific factors create unpredictable variability in response to anticancer therapy. For example, interindividual variations in absorption, distribution, or elimination could lead to sub- or supratherapeutic levels of anticancer agents and their metabolites. The genetic alterations that resulted in the cancer can also affect response. For example, breast cancers that overexpress HER2 are often sensitive to anthracycline-based regimens. As a result, both efficacy and tolerability can be affected. Healthcare professionals in oncology may preemptively modify doses based on variations in body size, blood counts, and organ function to optimize the effectiveness of therapy and minimize toxicity. However, more specific tools are becoming available as we learn how to identify and apply genetic differences. Pharmacogenomics is the study of the role of inheritance in individual variation of drug response. In oncology, several clinically relevant genetic polymorphisms or variations have been identified that can affect pharmacokinetics and pharmacodynamics. Examples include polymorphisms in genes responsible for the activity of the enzymes DPD (responsible for fluorouracil metabolism), TPMT and NUDT15 (responsible for thiopurine metabolism), UGT1A1 (responsible for irinotecan metabolism), and cytochrome P450 2D6 (responsible for tamoxifen metabolism). Patients with deficiencies in these enzymes can experience significant and possibly life-threatening toxicity. Identifying these genetic variants could permit individualization of regimens to reduce toxicity. Furthermore, pharmacokinetic and pharmacodynamic modeling is associated with improved responses and decreased toxicity in children with ALL.

The presence of other disease states (eg, comorbidities) may also affect response to treatment by limiting treatment options. The overall functional status of a patient may be assessed using performance status scales, such as the Karnofsky Performance Status and the Eastern Cooperative Oncology Group or ECOG scales (see Table 149-8). These scales can be used to predict patient tolerance of anticancer therapy and to assess the effects of therapy on the patient's level of activity and quality of life. For many cancers, performance status at diagnosis is the most important prognostic indicator.

TABLE 149-8

Assessing the Performance Status of Patients with Cancer

Eastern Cooperative Oncology Group (ECOG) Performance Status Scale		Karnofsky Performance Scale	
Grade	Description	Percent	Description
0	Fully active, able to carry on all pre-disease performance without restriction.	100	Normal, no complaints, no evidence of disease.
		90	Able to carry on normal activity; minor signs or symptoms of disease.
1	Restricted in physically strenuous activity, but ambulatory and able to carry out work of a light or sedentary nature (eg, light housework, office work).	80	Normal activity with effort; some signs or symptoms of disease.
		70	Cares for self; unable to carry on normal activity or to do active work.
2	Ambulatory and capable of all self-care, but unable to carry out any work activities. Up and about more than 50% of waking hours.	60	Requires occasional assistance but is able to care for most of personal needs.
		50	Requires considerable assistance and frequent medical care.
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours.	40	Disabled, requires special care and assistance.
		30	Severely disabled, hospitalization indicated. Death not imminent.
4	Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair.	20	Very ill, hospitalization and active supportive care necessary.
		10	Moribund.
5	Dead.	0	Dead.

Adapted from ECOG-ACRIN Cancer Research Group. ECOG Performance Status [cited 2021 July 18]. Available at: https://ecog-acrin.org/resources/ecog-performance-status.

Today's oncology healthcare professionals have a wealth of information to consider when designing a personalized treatment approach. Patient-specific factors (eg, performance status, comorbidities, organ function, and pharmacogenomics), tumor-specific factors (eg, pathology, stage, and biomarkers), and treatment goals (eg, palliation and cure) are all considered when determining the best treatment option. Treatment cost can also be an important consideration.

DRUG ADMINISTRATION

Dosage and Administration

Healthcare professionals should monitor all clinical and laboratory values that are affected by a specific anticancer agent at baseline and periodically during treatment. For example, a complete blood count should be evaluated weekly or before each cycle while receiving anticancer agents associated with myelosuppression. In general, an absolute neutrophil count, or ANC of 1,500 cells/mm^3 (1.5 × 10^9/L) or above, and a platelet count of 100,000 cells/mm^3 (100 × 10^9/L) or above are usually required before administering myelosuppressive agents. In addition, a chemistry panel is drawn to assess organ function, especially for agents eliminated or metabolized via those routes.

Anticancer agents might be dosed based on body size (such as body weight or body surface area [BSA]) or as a fixed (ie, flat) dose. Cytotoxic chemotherapy is generally dosed based on BSA. BSA is commonly used as an estimate of cardiac output and subsequent distribution to the liver and kidneys, the primary determinants of drug elimination. The most common methods used to determine BSA are the Mosteller and DuBois formulas. Traditionally, body-sized dosing has been used for mAbs but some agents, such as some immune checkpoint inhibitors, may use a flat dose. In contrast, most oral targeted agents are based on a fixed-dose approach.

Other dosing methods are being used to improve tolerability and anticancer activity. For example, carboplatin is dosed based on the patient's estimated glomerular filtration rate or GFR. This method is known as the Calvert formula and has been demonstrated to achieve adequate levels of carboplatin while minimizing excessive toxicity.

Molecular diagnostic tests are required prior to administration of some targeted agents (eg, trastuzumab, vemurafenib, and crizotinib), which are indicated only for patients whose tumors express a specific protein or gene. Additionally, health professionals must know how to interpret the findings from the various diagnostic tests. For example, some tests may identify if a tumor is mutation positive or negative, whereas other tests may identify the specific genetic alteration present in the tumor.

Safety and Handling

All anticancer agents regardless of the route of administration should be handled with care to avoid inadvertent exposure to healthcare professionals and caregivers. Consequently, all healthcare facilities should have written procedures for safely handling these agents, and all personnel should be oriented to these procedures. Healthcare professionals should provide information about safe handling and disposal to patients and their families when a patient is prescribed an oral anticancer agent. Patients should be informed of proper methods for disposing of potentially contaminated body excreta and cytotoxic waste. Safe handling includes avoiding skin contact and inhalation, but patient-centered guidelines regarding safe handling of oral anticancer agents have not been developed.

The United States Pharmacopeia regulates the preparation of extemporaneously compounded sterile preparations and should be used by healthcare professionals that prepare intravenous chemotherapy. Chapter 800 provides standards for the safe handling of hazardous agents in the healthcare setting. The most common avenue of exposure is via inhalation or skin absorption. Individuals preparing intravenous chemotherapy should work in an International Organization for Standardization, or ISO Class 5 biologic safety cabinet and wear appropriate personal protective equipment including a gown, face mask, eye protection, hair covers, shoe covers, and double sterile chemotype gloves. Closed-system vial-transfer devices should be used when possible. Negative-pressure techniques should be used in drug preparation to minimize aerosolization. Health professionals administering chemotherapy should take similar precautions to avoid exposure. Double chemotherapy-tested gloves, protective gowns, and protective eyewear (if there is potential for splashing) should be worn whenever handling or administering hazardous drugs. Kits for cleaning up chemotherapy spills should be located in all areas where chemotherapy is handled and cytotoxic waste should be disposed of properly.

ABBREVIATIONS

ADC	antibody-drug conjugate
ADCC	antibody-dependent cell-mediated cytotoxicity
ALL	acute lymphoblastic leukemia
ALK	anaplastic lymphoma kinase

αKG	alpha-ketoglutarate
AML	acute myeloid leukemia
ATP	adenosine triphosphate
BCL-2	B-cell lymphoma 2
BCR-ABL	breakpoint cluster region-Abelson
BRCA	breast cancer gene
BTK	Bruton's tyrosine kinase
CAR	chimeric antigen receptor
CD	cluster of differentiation
CDC	complement-dependent cytotoxicity
CDK	cyclin-dependent kinase
CLL	chronic lymphocytic leukemia
CML	chronic myeloid leukemia
CNS	central nervous system
CRS	cytokine release syndrome
CT	computed tomography
CTLA-4	cytotoxic T-lymphocyte–associated antigen 4
DHFR	dihydrofolate reductase
dMMR	mismatch repair deficient
DNA	deoxyribonucleic acid
DNMT	DNA methyltransferase
DPD	dihydropyrimidine dehydrogenase
ECG	electrocardiogram
EGFR	epidermal growth factor receptor
EML4	echinoderm microtubule-like protein 4
ER	estrogen receptor

ErbB	erythroblastic leukemia viral oncogene
ERK	extracellular signal-regulated kinase
FDA	Food and Drug Administration
FGFR	fibroblast growth factor receptor
FLT3	FMS-like tyrosine kinase 3
GEP-NET	gastroenteropancreatic neuroendocrine tumors
GIST	gastrointestinal stromal tumor
HBV	hepatitis B virus
HDAC	histone deacetylase
HER2	human epidermal growth factor receptor 2
HPV	human papilloma virus
HSCT	hematopoietic stem cell transplant
IDH	isocitrate dehydrogenase
irAE	immune-related adverse event
JAK	Janus kinase
KIT	stem-cell factor receptor
KRAS	kirsten ras
LVEF	left ventricular ejection fraction
mAb	monoclonal antibody
MAPK	mitogen-activated protein kinase
MDS	myelodysplastic syndrome
MEK	mitogen-activated protein kinase- extracellular signal-regulated kinase
MET	mesenchymal-epithelial transition
MRD	measurable residual disease
MSI-H	microsatellite instability-high
mTOR	mammalian target of rapamycin

NF-κB	nuclear factor-κB
NHL	non-Hodgkin lymphoma
NSCLC	non-small cell lung cancer
NTRK	neurotrophic receptor tyrosine kinase
NUDT15	nudix (nucleoside diphosphate linked moiety X)-type motif 15
PARP	poly ADP ribose polymerase
PD-1	programmed death-1
PD-L1	programmed death ligand-1
PDGF	platelet-derived growth factor
PDGFR	platelet-derived growth factor receptor
P-gp	p-glycoprotein
Ph	Philadelphia chromosome
Ph^+	Philadelphia chromosome-positive
PI3K	phosphatidylinositide 3-kinases
PPE	palmar-plantar erythrodysesthesia
RECIST	response evaluation criteria in solid tumors
REMS	risk evaluation and mitigation strategy
RET	rearranged during transfection
RNA	ribonucleic acid
SCLC	small cell lung cancer
SLAMF7	signaling lymphocytic activation molecule family 7
STAT	signal transducers and activators of transcription
TLS	tumor lysis syndrome
TNF-α	tumor necrosis factor-alpha
TPMT	thiopurine methyltransferase
TRK	tropomyosin receptor kinase

TROP2	trophoblast cell-surface antigen 2
UGT1A1	uridine diphosphate-glucuronosyl transferase 1A1
VEGF	vascular endothelial growth factor
VEGFR	vascular endothelial growth factor receptor
VTE	venous thromboembolism

SELF-ASSESSMENT QUESTIONS

1. Which of the following steps is part of the multistage process of carcinogenesis that involves further genetic alterations and increased cell proliferation?

   A. Transformation

   B. Promotion

   C. Propagation

   D. Progression

2. Which key characteristic allows cancer cells to become “immortal”?

    A. Activation of angiogenesis

    B. Undergoes apoptosis

    C. Activation of multiple oncogenes

    D. Activation of tumor suppressor genes

3. Which of the following statements *best* describes why cancer is difficult to treat?

    A. Homogeneous tumors with epigenetic mutations

    B. Heterogeneous tumors with multiple genetic and epigenetic mutations

    C. Homogeneous tumors with abnormal cytogenetics

    D. Heterogeneous tumors with normal cytogenetics

4. A 71-year-old individual is diagnosed with NSCLC. Tumor mutational analysis reveals an ALK mutation. Which of the following *best* describes the importance of the tumor mutational analysis result?

    A. Provides information on treatment strategies

    B. Predicts tolerability of therapy

    C. Provides information on ECOG performance status

    D. Provides information on stage of cancer

5. A 64-year-old individual is diagnosed with triple negative breast cancer (hormone receptor–negative and HER2-negative). The primary tumor in her left breast is 2 cm and she has 6 of 12 positive nodes. CT scan reveals a 2-cm tumor in her liver. MRI of brain is negative. Which of the following is the correct stage of cancer and goal of care?

    A. Stage I and goal of care is palliative.

    B. Stage II and goal of care is curative.

    C. Stage III and goal of care is curative.

    D. Stage IV and goal of care is to prolong survival.

6. Chemotherapy is resistant in which of the following phases of the cell cycle?

    A. S phase

    B. M Phase

    C. G_2 phase

    D. G_0 Phase

7. Small-molecule targeted agents interfere with which of the following?

    A. Extracellular receptors

    B. Signal transduction

C. Cell cycle

D. Immune response

8. A 33-year-old individual diagnosed with AML is admitted to the hospital for chemotherapy. After treatment, a bone marrow biopsy reveals the patient is in remission. Which of the following best describes the chemotherapy treatment?

A. Initial chemotherapy is considered induction therapy with a goal to put him in remission.

B. Initial chemotherapy is considered neoadjuvant therapy with a goal to make him a candidate for surgery.

C. Initial chemotherapy is considered adjuvant therapy with a goal to put him in remission.

D. Initial chemotherapy is considered consolidation therapy with a goal to put him in remission.

9. An average risk 50-year-old postmenopausal individual with no smoking history should be counseled regarding the following procedures as a part of routine cancer screening?

A. Cytology with HPV DNA test, every 5 years

B. Mammography, every 5 years

C. Colonoscopy, annually

D. Low-dose helical CT scan, annually

10. A 70-year-old individual is diagnosed with metastatic colon cancer. The oncologist recommends a chemotherapy regimen that consists of fluorouracil, oxaliplatin, leucovorin, and bevacizumab for 12 cycles. Which of the following statements describes characteristics of combination chemotherapy?

A. Incorporate agents with similar mechanisms of action and similar toxicity profiles.

B. Incorporate agents with different mechanisms of action and similar toxicity profiles.

C. Incorporate agents with similar mechanisms of action and different toxicity profiles.

D. Incorporate agents with different mechanisms of action and different toxicity profiles.

11. Which of the following *best* describes the difference between fam-trastuzumab deruxtecan and trastuzumab?

A. Trastuzumab is an antibody-drug conjugate and associated with more cardiotoxicity compared to fam-trastuzumab deruxtecan.

B. Fam-trastuzumab deruxtecan is an antibody-drug conjugate and associated with more cytotoxicity compared to trastuzumab.

C. Trastuzumab is a mAb and associated with more cytotoxicity compared to fam-trastuzumab deruxtecan.

D. Fam-trastuzumab deruxtecan is a mAb associated with similar cardiotoxicity compared to trastuzumab.

12. VEGFR inhibitors are commonly associated with which of the following adverse reactions?

A. Hypotension, QTc prolongation

B. Hypomagnesemia, acne-form rash

C. Hypothyroidism, bleeding

D. Hypertension, proteinuria

13. Which of the following agents is fatal if administered intrathecally?

    A. Hydrocortisone

    B. Cytarabine

    C. Vincristine

    D. Methotrexate

14. Which of the following immunotherapies mechanism of action includes: T-cell stimulation and proliferation?

    A. Ipilimumab

    B. Talimogene laherparepvec

    C. Sipuleucel-T

    D. Interleukin-2

15. Immune-related toxicities are reported with which of the following?

    A. Pembrolizumab

    B. Cetuximab

    C. Bevacizumab

    D. Talimogene laherparepvec

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** The first step in carcinogenesis is initiation, which requires exposure of normal cells to carcinogens. During the second step, known as promotion, carcinogens or other factors alter the environment to favor growth of the altered cell population compared to normal cells. At some point, the altered cell becomes cancerous (ie, transformation). The final stage, called progression, involves further genetic alterations that lead to increased cell proliferation. Propagation is not a step in the process of carcinogenesis. See the section "Etiology of Cancer."

2. **C.** Uncontrolled proliferation of cancer cells is due to genetic alterations that impact strict regulation of cell cycle, activation of oncogene, or suppression of tumor suppressor genes. Angiogenesis is the development of new blood vessels, which is a characteristic that supports growth of some cancers. See the section "Pathology of Cancer."

3. **B.** Malignant tumors are formed as a result of several genetic alterations that accumulate over time. The accumulation of genetic alterations leads to different genetic and/or epigenetic mutations which result in the heterogeneity of cancer. Heterogeneity of cancer leads to resistance to anticancer therapy. See the section "Etiology of Cancer" and "Systemic Therapy" subsections "Chemotherapy" and "Combination Therapy."

4. **A.** ALK is an oncogene that leads to uncontrolled proliferation. NSCLC that harbors an ALK mutation has specific treatment options available that target the ALK mutation and are associated with improved outcomes compared to other subtypes of NSCLC. Tumor mutational analysis does not provide information on stage of disease or predict tolerability of therapy. See the section "Diagnosis of Cancer" subsection "Clinical Presentation" and section "Targeted Agents: Small Molecules", subsection "Anaplastic Lymphoma Kinase (ALK) Inhibitors."

5. **D.** The patient has locally advanced cancer (positive lymph nodes) as well as distant metastasis in her liver. Therefore, she has stage IV cancer given the distant spread to the liver. The goal of care in stage IV disease is to prolong survival or provide palliation. See the section "Diagnosis of Cancer" subsection "Staging" and section "Treatment Modalities" subsection "Goals of Care."

6. **D.** The cells that are most sensitive to the effects of chemotherapy are rapidly dividing cells. These cells are always in the cell cycle. Chemotherapy

interferes with cellular division. Cells in the G_0 phase are not dividing and therefore resistant to the effects of chemotherapy. See the section "Pathology of Cancer" and "Systemic Therapy" subsection "Chemotherapy."

7. **B.** Small-molecule targeted agents inhibit kinases or enzymes responsible for activating various proteins involved in the intracellular signaling cascade. Monoclonal antibodies target extracellular receptors on the cell and chemotherapy targets cellular division via the cell cycle. Generally, the mechanism of action of a small-molecule inhibitor does not influence the immune system. See the section "Systemic Therapy" subsection "Targeted Agents" and section "Targeted Agents: Small Molecules."

8. **A.** Induction chemotherapy is high-dose combination chemotherapy with the intent to induce a remission or complete response. However, if chemotherapy is not continued then relapse will occur. Therefore, consolidation therapy is typically given after induction to maintain remission. Adjuvant therapy is systemic therapy administered to eradicate micrometastatic disease after local therapy (surgery or radiation). Neoadjuvant chemotherapy applies to tumors that are too large for surgical resection. AML is a hematologic malignancy; therefore, neoadjuvant therapy does not apply. See the section "Treatment Modalities."

9. **A.** Co-testing (cytology [Papanicolaou, or Pap, smear test] with HPV test) every 5 years, an annual mammogram, and a colonoscopy every 10 years would be appropriate for routine cancer screening in this patient. This patient should not be offered a low-dose helical CT scan as this lung cancer screening test should only be offered to current or former smokers 55- to 74-years old in good health with at least a 30-pack-year smoking history. See the section "Diagnosis of Cancer" and Table 149-4.

10. **D.** Combination chemotherapy is administered to treat cancer because of cancer heterogeneity and inherent resistance. Agents selected for combination regimens have demonstrated single agent activity and have different mechanism of actions to overcome different resistance patterns. In addition, agents selected should not have overlapping toxicity to avoid tolerability challenges. See the section "Systemic Therapy" subsection "Chemotherapy."

11. **B.** Fam-trastuzumab deruxtecan is an antibody-drug conjugate that consists of three components: antibody, linker, and cytotoxic payload. The cytotoxic payload contributes to the different adverse reaction profile compared to a mAb. Specifically, toxicity associated with the antibody-drug conjugate is a result of the cytotoxic payload as well as toxicity associated with the mAb. Fam-trastuzumab has a similar cardiotoxicity profile as trastuzumab; however, fam-trastuzumab is also associated with myelosuppression, given its cytotoxic payload. See the section "Targeted Agents: Antibodies" subsection "Antibodies That Target HER2."

12. **D.** VEGFR inhibitors are associated with proteinuria and hypertension. Other toxicities associated with VEGF inhibitors include wound healing complications, bleeding, VTE, and gastrointestinal perforation. See the section "Targeted Agents: Small Molecules" subsection "VEGFR multikinase inhibitors."

13. **C.** Vincristine is an antimicrotubule agent. It is fatal if given intrathecally, and the World Health Organization recommends administering it as an intravenous infusion. Methotrexate, cytarabine, and hydrocortisone are safe to be administered intrathecally. See section "Chemotherapy" subsection "Vinca Alkaloids" and Table 149-7.

14. **A.** Ipilimumab is a CTLA-4 inhibitor. CTLA-4 acts as a negative regulator of T-cell function, decreasing the ability of the immune system to mount an antitumor response. By binding to CTLA-4, ipilimumab allows for enhanced T-cell stimulation, proliferation, and antitumor activity. Talimogene laherparepvec is an oncolytic viral therapy based on a modified HSV type 1. Sipuleucel-T is a vaccine that does not regulate T-cell function. Interleukin-2 is a cytokine produced by recombinant DNA technology that promotes B- and T-cell proliferation and differentiation and initiates a cytokine cascade with multiple interacting immunologic effects. See the section "Immunotherapy."

15. **A.** Pembrolizumab is an immune checkpoint inhibitor. Immune checkpoint inhibitors release the breaks on the immune system and are therefore known to cause immune-related adverse events. See the section "Immunotherapy."

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 150: Supportive Care in Cancer

Amber B. Clemmons; Ashley E. Glode

KEY CONCEPTS

KEY CONCEPTS

① Myelosuppression (low blood counts), a common dose-limiting toxicity for numerous anticancer agents, is managed with blood product transfusions, colony-stimulating factors (CSFs), and/or anticancer therapy dose reduction or delay.

② Prevention of chemotherapy-induced nausea/vomiting (CINV) throughout the entire risk period is based on emetic risk of regimen, patient risk factors, and response. Management of chemotherapy-induced mucositis and diarrhea uses supportive care measures.

③ Tumor lysis syndrome (TLS) is one of the most common oncologic emergencies and warrants prophylaxis with hydration and either allopurinol or rasburicase depending on risk stratification and TLS management requires ongoing monitoring to correct electrolyte disturbances to prevent clinical sequelae, such as renal impairment, cardiac events, or seizures. Extravasation of intravenous (IV) chemotherapy requires prompt intervention, which may include antidote administration.

④ Immunotherapies are associated with unique immune-related adverse effects (irAEs) managed with immunosuppression (commonly corticosteroids) and dose delay or permanent discontinuation if necessary. Dose reduction is not a strategy used to manage irAEs.

⑤ Anticancer treatments which capitalize on the immune system, such as chimeric antigen receptor T cell (CAR-T) therapy, can cause cytokine release syndrome (CRS) and neurotoxicity, requiring close monitoring and prompt intervention with the anti-interleukin-6 agent tocilizumab and corticosteroid, respectively.

⑥ Patients may experience endocrine, cardiovascular, and ocular toxicities as a complication of cancer treatment; prompt identification and management are key to minimizing long-lasting adverse drug reactions (ADRs). Dermatologic toxicities from cancer treatment are broad in presentation, and accurate identification is important to determine appropriate supportive care interventions.

⑦ Osteopenia or osteoporosis from their anticancer treatment or bone fractures and pain from their malignancy metastasizing to bone are common. Prevention of skeletal-related complications is important to maintaining patient quality of life.

⑧ Venous thromboembolisms (VTEs) can be caused by malignancy, treatment, implanted devices (catheters or ports), and comorbidities, and both prevention and treatment are unique in patients with cancer. Routine prophylaxis is recommended in some scenarios, treatment of VTE should continue for at least 3 months or as long as the patient has active cancer or is receiving anticancer therapy, and only certain agents are recommended for prophylaxis and treatment.

⑨ Patients with cancer may be impacted by pain from various causes, including their disease or complications of cancer treatment and at different time points during their treatment.

⑩ Numerous long-term physical and psychological complications can occur after cancer treatment. Patients should be educated about potential risk for infertility and secondary malignancies from anticancer treatments.

BEYOND THE BOOK

BEYOND THE BOOK

Activity

Immune checkpoint inhibitors have revolutionized the treatment of patients with cancer. However, their unique toxicity profile brings a new challenge to the health professional. Oncologic societies have published multiple guidelines to aid in managing immune-related adverse events (irAEs). Please review the *National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines in Oncology* (NCCN Guidelines) for the "Management of Immunotherapy-Related Toxicities"[1] (https://www.nccn.org/professionals/physician_gls/pdf/immunotherapy.pdf). Based on these guidelines and the *National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events (CTCAE) v5.0* guidelines[2] (https://ctep.cancer.gov/protocoldevelopment/electronic_applications/docs/CTCAE_v5_Quick_Reference_8.5x11.pdf), please provide your recommendations on the case below.

This activity is helpful to enhance student understanding of the Assess, Plan, Implement, and Follow-Up steps in the patient care process.

Patient Case

AD is a 64-year-old patient with metastatic melanoma who presents to the clinic for cycle 5, day 1 of pembrolizumab. The chief complaint is a 3-day history of severe abdominal pain and "profuse diarrhea," which is estimated to be about 10 bowel movements per day (baseline = 1 bowel movement/day). There is tenderness to palpation on examination, but overall, you feel the symptoms are not life-threatening, afebrile and the patient denies blood in their stool. Based on vital signs and laboratory assessments, the patient is admitted to the inpatient oncology service. Workup suggests an inflammatory process in the colon, which you attribute to pembrolizumab.

PMH: Hypertension (HTN) diagnosed 3 years ago, metastatic melanoma diagnosed 5 months ago

Vitals: O_2sat: 98% (0.98) RA; HR 82 bpm; BP 99/51 mm Hg; 37.4°C

Labs: sodium 138 mEq/L (mmol/L; 136-145 mEq/L [mmol/L]); potassium 2.9 mEq/L (mmol/L; 3.4-5.1 mEq/L [mmol/L]); chloride 99 mEq/L (mmol/L; 98-107 mEq/L [mmol/L]); glucose 98 mg/dL (74-99 mg/dL) (5.4 mmol/L [4.1 - 5.5 mmol/L]); albumin 3.6 g/dL (3.5-5.2 g/dL) 36 g/L [35 - 52 g/L]); calcium 9.28 mg/dL (8.60-10.2 mg/dL) (2.32 mmol/L [2.15 - 2.55 mmol/L]); magnesium 1.34 mg/dL (1.61-2.60 mg/dL) (0.55 mmol/L [0.66 - 1.07 mmol/L]); phosphorous 2.0 mg/dL (2. 5-4.5 mg/dL) (0.65 mmol/L [0.81 -1.45 mmol/L]); creatinine 0.94 mg/dL (83 μmol/L;CrCl ~80 mL/min [1.33 mL/s]); ALT 28 U/L (0-33 U/L) (0.47 μkat/L [0 - 0.55 μkat/L]); ALT 23 U/L (0-32 U/L) (0.38 μkat/L [0 - 0.53 μkat/L]); T Bili 0.02 mg/dL (0-1.2 mg/dL) (0.3 μmol/L [0 -20.5 μmol/L])

Allergies: NKDA

Medication List: lisinopril 10 mg PO once daily; pembrolizumab 200 mg IV every 3 weeks

- Q1. Using NCI CTCAE v5.0, what grade of colitis is AD experiencing?
- Q2. Based on the NCCN guidelines, what is your initial treatment recommendation for this patient? Include any pharmacotherapy interventions and affiliated supportive care measures as well as plan for the current anticancer regimen.
- Q3. After 72 hours of treatment with your initial recommendation, AD's symptoms have not improved. What is your recommendation for the treatment of refractory colitis?

INTRODUCTION

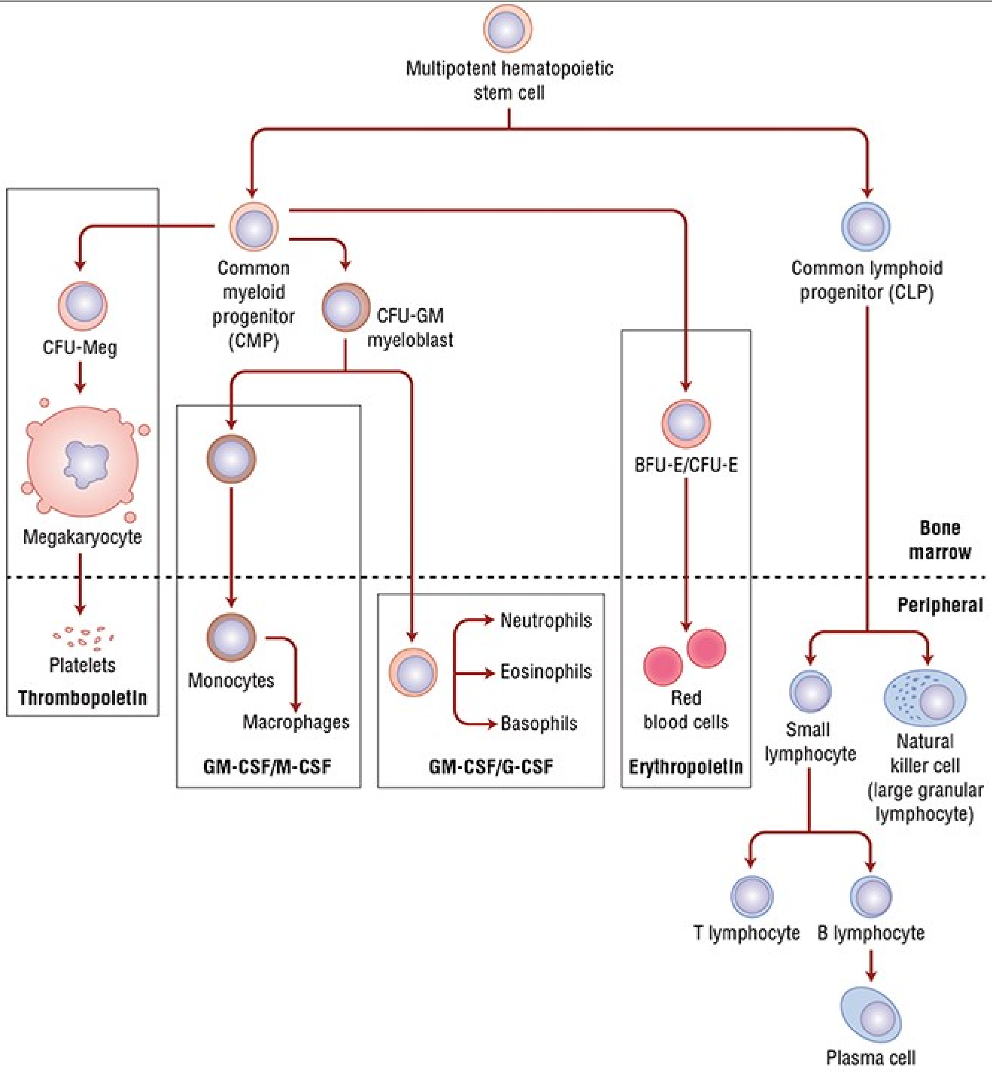
Anticancer treatments can result in numerous adverse drug reactions (ADRs), many of which may be life-threatening if not appropriately managed. ADRs (or toxicities) often relate to the agent's mechanism of action or "off-target" effects. Cytotoxic chemotherapy acts on rapidly dividing cells, often resulting in myelosuppression, gastrointestinal (GI) effects (mucositis, diarrhea, etc.), alopecia, and infertility. Biologic therapies and targeted small molecule agents have various ADRs, depending on the altered intracellular signaling, for example, rash with epidermal growth factor receptor (EGFR) inhibitors and hemorrhage or thrombosis with vascular endothelial growth factor (VEGF) inhibitors. Immunotherapies have a unique ADR profile, including autoimmune toxicities related to the modulation of the immune system. In general, toxicities are commonly graded via the Common Terminology Criteria for Adverse Events (CTCAE) scale from 0 (no toxicity) to 5 (death).[2] The principles of preventing and managing some of the most common and severe ADRs associated with anticancer therapies are detailed below.

HEMATOLOGIC TOXICITIES: ANEMIA, NEUTROPENIA, AND THROMBOCYTOPENIA

Normal hematopoiesis consists of several well-orchestrated steps. Pluripotent stem cells differentiate, proliferate, and maturate to allow the formation of the blood cells seen in the peripheral circulation. Specifically, myeloid stem cells give rise to erythrocytes, platelets, monocytes, basophils, neutrophils, and eosinophils. In contrast, lymphoid stem cells give rise to B-lymphocytes, T-lymphocytes, and natural killer cells (Fig. 150-1).

FIGURE 150-1

Schematic of hematopoiesis with site of action of targetable hematopoietic growth factors. Multipotent hematopoietic stem cells (HSCs) differentiate in the bone marrow into common myeloid or lymphoid progenitors (CMP, CLP) which ultimately generate all mature blood cells. In the lymphoid lineage, the CLP gives rise to B cells, T cells, and natural killer (NK) cells. In the myeloid lineage, the CMP gives rise to several colony forming units (CFUs) and burst forming units (BFUs) that result in the creation of platelets (also called thrombocytes), red blood cells (also called erythrocytes), and myeloblast cells (which further give rise to neutrophils, basophils, eosinophils) as well as monocytes (which become macrophages). Numerous hematopoietic growth factors influence the self-sustaining HSCs to differentiate into these various cells; notably, further differentiation of myeloblasts, megakaryocytes, and erythrocytes can be stimulated by granulocyte colony-stimulating factor (G-CSF) or monocyte/macrophage-stimulating factor (M-CSF), thrombopoietin, and erythropoietin, respectively.



Multipotent hematopoietic stem cell
Common myeloid progenitor (CMP)
CFU-GM myeloblast
Common lymphoid progenitor (CLP)
CFU-Meg
Megakaryocyte
Platelets
Thrombopoietin
Monocytes
Macrophages
GM-CSF/M-CSF
Neutrophils
Eosinophils
Basophils
GM-CSF/G-CSF
BFU-E/CFU-E
Red blood cells
Erythropoietin
Bone marrow
Peripheral
Small lymphocyte
Natural killer cell (large granular lymphocyte)
T lymphocyte
B lymphocyte
Plasma cell

Myelosuppression, depressed bone marrow function resulting in low blood counts—anemia, neutropenia, and thrombocytopenia—can occur due to cancer invasion in bone marrow or after various anticancer therapies. Myelosuppression is typically not an immediate effect because the circulating blood cells must first be killed by the anticancer treatment or used by the body. For example, neutropenia typically occurs first because white blood cells (WBCs) have a short lifespan of 6 to 12 hours, followed by thrombocytopenia as platelets have a lifespan of 5 to 10 days. Anemia typically occurs late since erythrocytes have a relatively long lifespan of 120 days. The lowest blood cell count (or nadir) typically occurs 10 to 14 days after cytotoxic chemotherapy administration, with a recovery in cell counts occurring by 3 to 4 weeks after administration, or later depending on the agent (eg, nitrosoureas and radiolabeled monoclonal antibodies at 4-6 weeks). Patients with leukemia or receiving a hematopoietic stem cell transplantation (HSCT) typically have a more rapid nadir of approximately 5 to 7 days due to the intensity of therapy utilized in these conditions and the nature of the disease. In many scenarios, subsequent doses should be delayed until minimum suggested blood counts (eg, absolute neutrophil count [ANC] ≥ 1,000-1,500 cells/mm^3[$1 \times 10^9 – 1.5 \times 10^9$/L], platelets ≥ 100,000/μL [100×10^9/L]) are achieved to minimize additional toxicity and morbidity. Dose reductions may be considered empirically based on baseline myelosuppression or, more commonly, during treatment based on either prolonged recovery of counts or severe myelosuppression warranting intervention (transfusions/occurrence of neutropenic fever). However, clinicians must balance dose reduction with treatment goals since reduced treatment intensity can compromise efficacy in certain disease states (eg, breast cancer, lymphoma). Clinicians accept some myelosuppression if it is not compromising the patient’s quality of life, and the cancer is responding to therapy. In patients where cure is commonly the goal, the empiric use of hematopoietic growth factor products (also called colony-stimulating factors [CSFs]) provides an alternative to dose reduction.

Neutropenia

Neutropenia is associated with an increased risk of infection, the probability of which increases when ANC is <500 cells/mm^3 (0.5 × 10^9/L) or when the duration of neutropenia is prolonged (>7-10 days). Other risk factors for infection include alteration in the integrity of physical defense barriers and the functional integrity of the leukocytes, which can be affected by underlying cancer, anticancer agent, or radiation therapy (RT).

Infections are difficult to identify in the neutropenic patient since usual signs and symptoms of infection (eg, purulent drainage) are often absent. Therefore, clinicians heavily rely on fever as an indicator of infection in these patients. Prompt initiation of empiric antibiotics, based on likely organisms from patient presentation and history and local antibiogram, is paramount to prevent mortality. The most common source of infection in these patients is self-infection with body flora, which includes both gram-positive and gram-negative bacteria. Specific treatment of infections in immunocompromised hosts is discussed in Chapter 145, "Infections in Immunocompromised Patients."

CSF products may minimize the severity of neutropenia and subsequently reduce the risk of infection. These products provide proteins essential for the normal growth and maturation of blood cell components (Fig. 150-1). Filgrastim stimulates the production of neutrophilic granulocytes, and sargramostim promotes the proliferation of granulocytes (neutrophils and eosinophils), monocytes, and macrophages. Although sargramostim stimulates megakaryocytes, no consistent effect on platelet production has been observed in trials, and this agent is not commonly used in clinical practice. Both CSFs initially enhance demargination and mobilization of mature cells from the marrow and then provide constant stimulation of stem cell progenitors. Pegfilgrastim is a pegylated form of filgrastim with a substantially longer half-life allowing for single-dose administration compared to daily doses of filgrastim. A pegfilgrastim device is available, which can be placed immediately after the end of chemotherapy to auto-inject the dose of pegfilgrastim 24 hours later. Several biosimilar CSF products are also available and generally considered interchangeable.[3]

For optimal efficacy, CSFs should be started between 24 and 72 hours after chemotherapy. Filgrastim and sargramostim can be stopped the day before chemotherapy, whereas pegfilgrastim should not be administered within 12 days before the next dose of chemotherapy due to its extended half-life.[3] CSFs should not be administered within 14 days of chimeric antigen receptor T cell (CAR-T) due to increased risk of cytokine release syndrome (CRS).[3] Subcutaneous administration is preferred for CSFs. Because of the high cost of these agents, doses of filgrastim are commonly rounded to the nearest product vial size to minimize waste.

CSFs are generally well tolerated, with the most common ADR being bone pain, which can be mitigated with routine concomitant use of an antihistamine, such as loratadine and/or pain medications such as nonsteroidal anti-inflammatory agent naproxen, if no contraindicating factor exists, for the week after CSF administration.[3] Other ADRs include constitutional symptoms (low-grade fever, myalgia, headache, etc.), injection site reactions, and generalized maculopapular rash, with a rare but serious ADR of splenic rupture.

Guidelines exist regarding appropriate use of CSFs for prophylaxis of neutropenia based on the propensity of a regimen to cause febrile neutropenia (FN), which can also be determined from safety results in clinical trial reports.[3,4] Primary prophylaxis, the prevention of neutropenia with the first cycle of chemotherapy, is recommended for patients receiving a chemotherapy regimen with ≥20% risk of FN.[3,4] Most dose-dense chemotherapy regimens require CSF support to maintain dose intensity and schedule.[3] Additionally, primary prophylaxis can be considered for patients with at least one risk factor who are receiving a chemotherapy regimen with a 10% to 20% risk of FN (intermediate risk). Patient risk factors include age at least 65 years receiving full chemotherapy dose intensity, previous chemotherapy or RT, persistent neutropenia, bone marrow involvement of tumor cells, recent surgery and/or open wounds, liver dysfunction, and renal dysfunction. Secondary prophylaxis refers to the prevention of recurrent neutropenia in patients who had experienced a neutropenic complication (eg, FN) with the prior cycle of chemotherapy. Secondary prophylaxis is generally reserved for patients with chemosensitive cancers where a dose reduction or delay may affect survival. In other scenarios, dose reduction or delay in chemotherapy may be utilized instead of CSFs. Re-evaluation of FN risk is warranted after each cycle and at changes in therapy. CSFs are not recommended for neutropenic patients who are afebrile or routinely for management of FN. However, they may be considered for high-risk patients based on clinical judgment and patient-specific risk factors.[3,4] The use of CSFs in pediatric oncology patients is guided by clinical protocol.

Regarding patients with myeloid malignancies, since myeloid blast cells have receptors for granulocyte CSF and granulocyte-macrophage CSF, some experts were initially concerned that the use of CSFs would stimulate the regrowth of leukemia. Although subsequent studies have addressed these concerns and CSFs can be considered after initial induction therapy (although beneficial impact is deemed to be modest), many clinicians do not initiate filgrastim until an initial remission is achieved. CSFs are used following consolidation therapy in adult patients with acute leukemia. Notably, the use of CSFs can interfere with the interpretation of the day 14 bone marrow examination in this population (ie, may see immature myeloid forms erroneously suggesting residual disease); therefore, CSFs should be discontinued at least 7 days before a bone marrow biopsy.[5] Growth factors are not recommended in patients with acute promyelocytic leukemia during induction therapy due to increased risk of differentiation syndrome.[5]

Other uses for CSFs include peripheral blood stem cell mobilization protocols (notably, higher doses than used for prophylaxis) and the management of congenital or idiopathic neutropenia. In patients undergoing HSCT, CSFs have also proven effective in accelerating engraftment and treating graft failure; therefore, they are recommended postautologous HSCT and can be considered postallogeneic HSCT.[4] CSFs should be used with caution in patients receiving concomitant chemotherapy and RT, especially if the RT involves the mediastinum, as these patients appear to experience more significant thrombocytopenia.

Trilaciclib is a first-in-class myeloprotective agent approved for patients with extensive stage small cell lung cancer with ongoing trials for patients diagnosed with other malignancies. When administered before chemotherapy, trilaciclib arrests hematopoietic stem and progenitor cells in the G1 phase to prevent cellular damage from the cytotoxic chemotherapy. It is administered intravenously on each day of chemotherapy administration. The most common adverse effects are fatigue, hepatotoxicity, and electrolyte imbalances (calcium, potassium, and phosphate). Trilaciclib has several drug-drug interactions, including with cisplatin which may result in increased risk of nephrotoxicity.[6]

Anemia

Anemia is a common complication after cytotoxic chemotherapy and various tyrosine kinase inhibitors (TKIs), such as those targeting EGFR, human epidermal growth factor receptor 2 (HER2), and VEGF. Incidence varies by cancer type and stage as well as dose and duration of therapy. Further, patient-specific factors may contribute to nutritional deficiencies (ie, iron, folate, vitamin B12), receipt of RT, renal dysfunction, and anemia of chronic disease. Fatigue is the most common symptom of anemia, with some patients reporting other symptoms such as shortness of breath. Other causes of fatigue should be considered, such as insomnia, depression, unrelieved pain, and underlying malignancy.

The mainstay of treatment of symptomatic or severe chemotherapy-induced anemia is red blood cell transfusion. Transfusions of packed red blood cells (PRBCs) are generally indicated for hemoglobin <8 g/dL (80 g/L; 4.97 mmol/L) or higher if the patient is experiencing extreme fatigue or dyspnea, tachycardia, or chest pain. Erythropoiesis-stimulating agents (ESAs; epoetin alfa, darbepoetin alfa) may be considered in patients with underlying kidney disease and those receiving palliative treatment who have a hemoglobin <10 g/dL (100g/L; 6.21 mmol/L). ESAs are restricted to these populations due to serious ADRs, including thrombosis and myocardial infarction, and increased risk of mortality in patients with cancer. Other ADRs of ESAs include injection site reactions, rash, flu-like symptoms, and HTN . Therefore, the risk and benefits of ESA use must be discussed with patients in advance. Generally, these ADRs occurred when the target hemoglobin of 12 g/dL (120 g/L; 7.45 mmol/L)is exceeded or hemoglobin rises too rapidly. Evaluation for iron deficiency is advised before initiating ESA with appropriate ongoing laboratory monitoring. If ESAs are utilized, the goal is to achieve the minimum hemoglobin needed to avoid transfusions. ESAs should not be used for nonchemotherapy-induced anemia, except for select patients with myelodysplastic syndrome. Clinical practice guidelines for cancer and chemotherapy-induced anemia are available.[3,7]

Thrombocytopenia

Thrombocytopenia associated with chemotherapy increases the risk for significant bleeding. The mainstay of management is platelet transfusion which is administered to patients with platelet count < 10,000 cells/mm^3 (10 × 10^9/L) or higher if patient is experiencing active bleeding, undergoing an invasive procedure, has coagulation abnormalities (eg, acute promyelocytic leukemia), or has fever/documented infection.[8] Alloimmunization rarely occurs due to antibodies against human leukocyte antigen (HLA) antigens; in these scenarios, histocompatible donors must be utilized.

GI TOXICITIES: DIARRHEA, MUCOSITIS, AND NAUSEA/VOMITING

Diarrhea

Mucosal damage can occur at any point along the entire length of the GI tract. In the lower portion of the GI tract, this usually manifests as diarrhea and abdominal pain although onset of symptoms varies by inciting agent (eg, generally within a few days of cytotoxic chemotherapy versus delayed after immunotherapy). Monitoring includes stool count per day, electrolytes, and fluid balance since supplementation may be necessary. After infectious causes have been ruled out, mild-to-moderate diarrhea can safely be treated with loperamide (up to 2 mg every 2 hours), with oral antibiotics and/or octreotide for persistent diarrhea (≥48 hours). Adjunctive diphenoxylate/atropine (diphenoxylate 5 mg four times a day; maximum 20 mg per day) can also be used. Nonpharmacologic interventions include cessation of products containing lactose, alcohol, or high-osmolar supplements with addition of clear liquids and small frequent meals; the BRAT diet (banana, rice, applesauce, toast) may also be considered. Severe or complicated diarrhea (dehydration, hypotension, bleeding, fever, neutropenia, severe cramping, unresponsive to intervention, etc.) warrants hospital admission with hydration, antibiotics, and the somatostatin analog octreotide; notably, anticancer treatment often needs to be held.[9]

Certain anticancer agents are known to commonly cause diarrhea. Irinotecan and sacituzumab govitecan can cause both acute diarrhea, occurring in first 24 hours and managed with atropine to counteract the underlying cholinergic mechanism, while delayed diarrhea, which occurs after 24 hours, is managed supportively as per above. Other agents that commonly induce diarrhea are 5-fluorouracil, capecitabine, certain targeted chemotherapy agents (eg, imatinib and EGFR, HER2, VEGF, phosphoinositide-3 kinase [PI3K], cyclin-dependent kinase, or CDK4/6, inhibitors) and immune checkpoint inhibitors (ICIs) see "Immune-Related Adverse Events" section. Management of diarrhea may vary by agent and its route of administration.

Mucositis

Due to rapid cellular turnover, the GI mucosa is a common site of toxicity associated with anticancer therapy, particularly cytotoxic chemotherapy agents (eg, fluorouracil, methotrexate) and agents, such as multikinase and mammalian target of rapamycin (mTOR) inhibitors. The subsequent inflammation (mucositis) can lead to painful ulcerations and an inability to eat, drink, or swallow. Disruption of the GI mucosal barrier may also provide an avenue for systemic microbial invasion and infection.

Prevention of mucositis is mainly through good oral hygiene. High-risk patients (poor dentition, high-dose chemotherapy, or RT involving the oropharynx) should undergo a dental evaluation before starting therapy and use mouth rinses (baking soda and salt water or plain saline rinses) during therapy.[10] Oral cryotherapy is recommended before certain chemotherapy, such as high-dose melphalan and 5-fluorouracil, to provide vasoconstriction in prevention of drug delivery to mucosal tissue. Prevention with palifermin, a keratinocyte growth factor, can be considered for patients receiving specific HSCT regimens.[11] Dexamethasone mouthwash can be utilized for mTOR-associated mucositis.[12]

After mucositis has developed, treatment is mainly supportive, including use of topical or systemic analgesics. Despite insufficient data, numerous formulations of "magic mouthwash" are commonly used in clinical practice. There are commercially available products, or a compound can be made often including ingredients of viscous lidocaine, diphenhydramine, and liquid antacid. Severe mucositis may lead to dehydration and require IV hydration and opioid analgesics, with prolonged severe cases also warranting evaluation for IV nutrition. Local infections caused by *Candida* species and herpes simplex virus (HSV) can occur; therefore, suspicious lesions should be cultured and appropriate antifungal or antiviral treatment initiated. Mild infections (ie, thrush) may be treated with topical antifungal therapy, such as clotrimazole troches or nystatin oral suspension, whereas more severe oral or esophageal fungal infections require systemic antifungal treatment (see Chapter 144, "Invasive Fungal Infections").

Nausea/Vomiting

Introduction

chemotherapy-induced nausea/vomiting (CINV) is the nausea/vomiting (N/V) associated with the administration of chemotherapy, which is a physiologic and psychological process. The impact of CINV on quality of life is substantial. Unless adequately prevented and managed, CINV can lead to adverse outcomes such as metabolic derangements, nutritional depletion, anorexia, weight loss, premature withdrawal of anticancer treatment, and/or degeneration of self-care and functional ability.[13]

Antiemetic prophylaxis is based on emetogenicity, the likelihood an agent will induce N/V,[14] although this can be tailored by patient risk factors (age <50 years, female, history of motion or morning sickness, prior poor CINV control, and depression or anxiety) and prior lack of response to antiemetics.[13] Guidelines divide IV anticancer therapies into four risk categories: highly emetogenic chemotherapy (HEC), moderately emetogenic chemotherapy (MEC), low emetogenic chemotherapy (LEC), and minimally emetogenic, which causes CINV in > 90%, 30% to 90%, 10% to 30%, and <10% of patients, respectively.[13] Oral anticancer therapy is classified as minimal-to-low if <30% risk or moderate-to-high risk if ≥30% risk.[13]

Pathophysiology and Definitions

Chemotherapy damages enterochromaffin cells lining the GI tract which releases serotonin. This process is the peripheral pathway, originating outside the central nervous system (CNS) and occurs within 24 hours of chemotherapy administration (acute CINV). Secondarily, chemotherapy alters the modulation of dopamine and substance P in the CNS. This process is the central pathway that originates within the CNS and occurs within 24 to 72 hours after chemotherapy administration (delayed CINV)[15] (see Chapter 53, "Nausea and Vomiting," Fig. 53-1). CINV can also be classified as anticipatory (conditioned response occurring before chemotherapy begins), breakthrough (occurs within 5 days of prophylactic antiemetics and requires rescue therapy), refractory, or chronic.

Presentation and Evaluation/Monitoring

Clinical presentation of CINV can include more than just emesis and/or nausea. Patients may also present with poor oral intake, malnutrition, weight loss, abdominal discomfort, dehydration, and dizziness. Monitoring should include laboratory markers of serum electrolytes and renal function as well as assessment of fluid status (input and output), blood pressure (BP; orthostatic hypotension), and medication history.

When evaluating CINV, providers must rule-out other potential causes of N/V. The differential diagnosis may include fluid and electrolyte abnormalities, volume depletion, hypercalcemia, drug-/opiate-induced, GI obstruction, increased intracranial pressure, brain or meningeal involvement, uremia, and infection.[15] Ongoing monitoring should include emesis count, nausea score (usually a visual analog scale, or VAS), electrolytes, fluid balance, oral intake, and medication use.

Prevention and Treatment

Several antiemetic guidelines exist (American Society of Clinical Oncology [ASCO], National Comprehensive Cancer Network [NCCN]); however, variation exist across guidelines, which may partially be due to the information available at the time of guideline publication. Some examples of differences across guidelines with respect to the classification of emetic risk (eg, carboplatin AUC ≥ 4), preference for 5-hydroxytryptamine/serotonin receptor antagonist (5-HT3-RA) agent in MEC doublet, strength of recommendation for four-drug prophylaxis in HEC and HSCT, duration of dexamethasone in certain regimens, olanzapine dose, management of breakthrough CINV, and recommendation for adjunctive agents.[13,14] Therefore, clinicians should consider these variations when implementing recommendations in practice.

Antiemetic prophylaxis is determined by risk category: HEC, quadruplet (or triplet, per NCCN); MEC, doublet (or triplet, per NCCN); LEC, monotherapy; minimal, no prophylaxis (Table 150-1). The primary goal of prevention is no vomiting and no nausea throughout the risk period. The duration of emetic risk is 2 days for MEC and 3 days for HEC—antiemetics should be initiated before any chemotherapy with ≥10% risk (generally 30 minutes before) and administered through risk period.

TABLE 150-1

CINV Prophylaxis for IV Chemotherapy Regimens

CINV Prophylaxis Regimen Definitions			
Quadruplet Therapy	**Triple Therapy**	**Doublet Therapy**	**Monotherapy**
5-HT3-RA + steroid +NK1-RA + olanzapine	5-HT3-RA + steroid + NK1-RA *or* olanzapine	5-HT3-RA + steroid Optional: triplet regimen based on patient-specific risk factors (ie, NK1-RA- or olanzapine-based triplet)	5-HT3-RA *or* dexamethasone (per ASCO) *or* metoclopramide *or* prochlorperazine (per NCCN) *All ONCE Doses

CINV Prophylaxis Recommendations for IV Chemotherapy[14]		
Risk	**Phase**	**Prophylaxis**
HEC	Acute Phase	Quadruplet: 5-HT3-RA + dexamethasone + NK1-RA + olanzapine
	Delayed Phase	Olanzapine on days 2-4 If used on day 1, oral aprepitant continues days 2-3 If regimen other than AC, dexamethasone continues days 2-3 (dose varies by which NK1 utilized)
MEC	Acute Phase	Doublet: 5-HT3-RA + dexamethasone
	Delayed Phase	Dexamethasone 8 mg PO/IV on days 2-3 only if patients receiving therapies with known potential for delayed CINV
LEC	Acute Phase	Monotherapy: 5-HT3-RA or dexamethasone
	Delayed Phase	None
Minimal	Acute Phase	None
	Delayed	None

AC, anthracycline + cyclophosphamide; NK1-RA, neurokinin-1 receptor antagonist.

Notes: Per ASCO guideline,[14] carboplatin with AUC ≥ 4 specifically warrants prophylaxis in acute phase with 5-HT3-RA + Dex + NK1-RA and none in delayed phase. When given at equipotent doses, oral and IV serotonin receptor antagonists are equivalent in efficacy.

Patients receiving multiday chemotherapy regimens should be provided antiemetics appropriate for the agent with highest emetogenicity on each day chemotherapy administered and for the risk period after completion of the regimen, which depends on emetogenicity of last agent(s) administered. For example, a triplet antiemetic therapy is used for 4- to 5-day cisplatin regimens. In patients undergoing HSCT conditioning regimens, triplet or quadruplet antiemetic therapy is recommended.[14]

Oral Anticancer Therapy-Induced N/V

The antiemetic risk of oral anticancer therapies is divided into two categories: moderate-to-high risk (≥30%) versus minimal-to-low risk (<30%). Prophylaxis for moderate-to-high risk is a 5-HT3-RA given 30 minutes before anticancer therapy each day. Prophylaxis for minimal-to-low risk is an as-needed antiemetic agent (5-HT3-RA, prochlorperazine, or metoclopramide). Although if CINV does occur, a scheduled antiemetic before anticancer therapy is recommended.[13] Practical issues must be taken into consideration when choosing a prophylaxis regimen for oral anticancer therapy regimens including setting (inpatient versus outpatient) and available route(s) of administration, overlap with IV regimens, duration of risk period and antiemetic duration of efficacy, tolerability of prolonged antiemetic use, and adherence. Administration of prophylaxis and associated oral anticancer therapy at nighttime may be considered to improve tolerability.

Radiation-Induced N/V

The prevention of radiation-induced N/V is also based on emetogenic risk, which is dependent on the anatomic site of RT.[14] The optimal medication, dosing, and duration of prophylaxis regimen is unknown. Highly emetogenic RT includes total body irradiation (TBI), for which ondansetron or granisetron plus dexamethasone prophylaxis is recommended. For moderate risk, such as RT to upper abdomen or craniospinal, ondansetron, or granisetron before each fraction as well as dexamethasone before first five fractions is recommended. For minimal and low risk RT, rescue therapy is recommended.[14]

Regarding those receiving concomitant RT and chemotherapy, antiemetic prophylaxis is based on the emetogenic risk of the chemotherapy regimen, unless the emetogenic risk level of RT is higher, and continuing prophylaxis appropriate for RT if it continues beyond the end of chemotherapy prophylaxis period.[13,14]

Anticipatory CINV

Anticipatory N/V is often a result of prior negative experience. Patient education is critical: first, educate on what prophylaxis is being offered to alleviate fear; second, educate on specific management strategies for coping with CINV. For example, behavioral therapy can be employed and if benzodiazepine is prescribed; this can be administered 30 minutes before arriving to ambulatory care treatment center or before meals, depending on association of event/food with onset of nausea. Often, lorazepam 0.5 to 2 mg oral (PO)/IV every 4 to 6 hours or pre-meals is utilized in clinical practice.

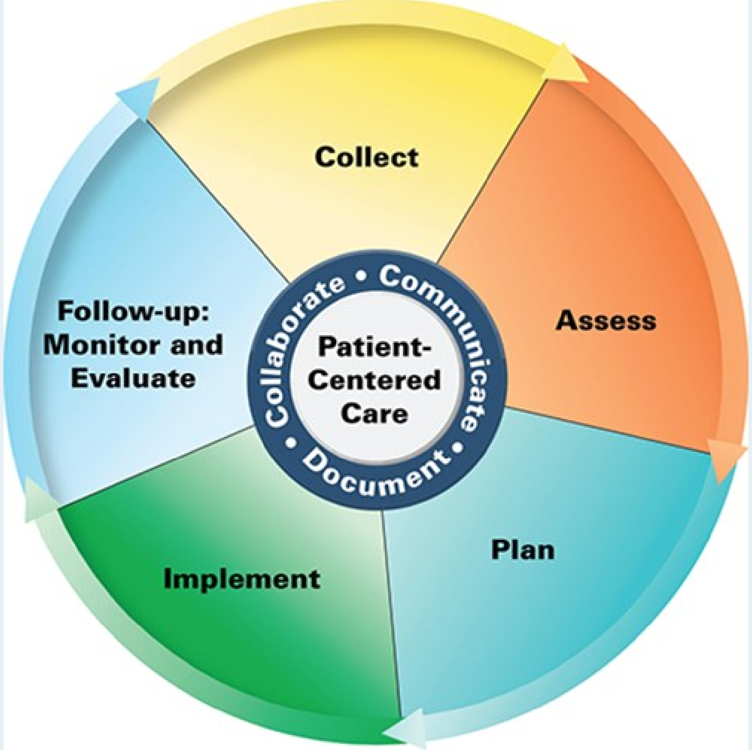
Management of Breakthrough and Refractory CINV

All patients should be provided with breakthrough (PRN) medication and instructed to take as soon as feel nauseated or have emesis. Choice of breakthrough agent may vary in practice, although selecting an agent not previously given as prophylaxis and consideration of toxicities of antiemetics are key considerations. Options include olanzapine, phenothiazine, metoclopramide, dronabinol, scopolamine patch, haloperidol, 5-HT3-RA, dexamethasone, or benzodiazepine.

If breakthrough occurs, future cycles should be adjusted (ie, increase prophylaxis).[13] Specifically, if olanzapine was not previously included in prophylaxis it should be added.[14]

PATIENT CARE PROCESS

Patient Care Process for Supportive Care in Cancer



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

The patient care process for tumor lysis syndrome (TLS). See “Oncologic Emergencies: TLS and Extravasation” section and Table 150-2.

Collect

- Patient demographic factors including concomitant medications, cancer diagnosis, and current/impending anticancer treatment intervention(s) along with their affiliated TLS risk category
- Laboratory markers: potassium, SCr, calcium, phosphorus, and uric acid

Assess

- Urine output and hydration status
- Presence of cardiac arrhythmias or seizure activity (ie, obtain ECG and EEG if warranted)
- Presence of symptoms of hyperkalemia (eg, muscle cramps), hypocalcemia (eg, paresthesia), hyperphosphatemia (eg, lethargy), and/or hyperuricemia (eg, oliguria/anuria)

Plan*

- Drug therapy regimen to include hydration with allopurinol for intermediate-risk or rasburicase for high risk. Additionally, add interventions for specific laboratory TLS as indicated (eg, phosphorus binder for hyperphosphatemia)
- Monitoring above laboratory parameters as per risk level

Implement

- Patient education on symptoms of clinical TLS
- Schedule follow-up laboratory monitoring as per risk level

Follow-Up: Monitor and Evaluate

- Ongoing laboratory monitoring (at least daily or more frequently if intermediate to high risk or active clinical TLS)
- Resolution of any signs/symptoms and ongoing clinical assessment for renal, cardiac, and/or neurologic changes

[*] *Collaborate with patient, caregivers, and other healthcare professionals.*

ONCOLOGIC EMERGENCIES: TLS AND EXTRAVASATION

Oncologic emergencies are a diverse group of acute complications associated with cancer pathophysiology itself and/or the initiation of anticancer treatments. These situations may be the presenting reason for acute hospitalization whereby a diagnosis of cancer is made or may occur at any time during a patient's course of management. Prompt identification and adequate initial treatment are critical to prevent morbidity and mortality. Many complications are considered oncologic emergencies, including TLS and extravasation, which are detailed below. Other oncologic emergencies are beyond the scope of this chapter but include hypersensitivity reaction (see Chapter e108, "Drug Allergy"), FN (see Chapter 145, "Infections in Immunocompromised Patients"), hypercalcemia of malignancy (see Chapter 69, "Calcium and Phosphorus Homeostasis"), malignant spinal cord compression, superior vena cava syndrome, malignant pericardial effusion, malignant airway obstruction, disseminated intravascular coagulopathy, hyponatremia, hyperviscosity syndrome, and leukocytosis.[16,17]

Tumor Lysis Syndrome

TLS is the most common disease-related oncologic emergency. TLS occurs due to the rapid destruction of cells either spontaneously from cancer progression or due to effects of antineoplastic therapy.[18] The lysis of cells releases intracellular contents leading to catabolism of nucleic acids, which results in hyperuricemia while the release of potassium and phosphorus leads to hyperkalemia, hyperphosphatemia, and secondary hypocalcemia. Urate or phosphorus-calcium crystals can cause renal insufficiency while hyperkalemia can cause cardiac disturbances and hyperphosphatemia can lead to seizures. Laboratory TLS is defined by the Cairo-Bishop Criteria[73] (Table 150-2) while clinical TLS is the presence of laboratory TLS plus at least one of the following: renal impairment (serum creatinine [SCr] ≥ 1.5 × ULN), cardiac arrhythmias, or seizures. Cairo-Bishop grading scale for TLS evaluates level of renal impairment, cardiac arrhythmia, and seizure activity on a grade 0 to 5 scale.[18] Risk factors are patient-related (pre-existing conditions such as dehydration, hypotension, acidosis, renal or cardiac disease) and disease-related (cancer diagnosis, tumor burden – bulky tumor > 10 cm or WBC > 25 × 10^3/μL (25 × 10^9/L), elevated lactic dehydrogenase, high proliferation rate, chemotherapy sensitivity). While lactic dehydrogenase is a surrogate marker for cell turnover rate and can therefore be a component in risk assessment, it is not part of diagnosis of TLS.[19] TLS occurs most commonly in patients with aggressive hematologic malignancies, such as high-grade lymphomas or acute leukemias. Incidence varies widely depending on cancer and treatment type. Notably, TLS can occur not just after traditional cytotoxic IV chemotherapy, but also after RT, oral chemotherapy, or targeted therapy (eg, monoclonal antibodies).[20] TLS often occurs within 12 to 72 hours of initiation of antineoplastic therapy, although it can occur later depending on the antineoplastic agent's onset of activity or spontaneously prior to treatment initiation.

TABLE 150-2

Tumor Lysis Syndrome: Definition, Presentation, and Management

Laboratory TLS[a]	**Symptoms/Signs**	**Management Strategies**
Uric acid ≥ 8 mg/dL (476 μmol/L) or > 25% ↑ from baseline	• Obstructive uropathy, hematuria, flank pain, lethargy, oliguria, or anuria	• Prevention: hydration, allopurinol (or potentially febuxostat); consider for low risk and optional for intermediate risk • Management: continue hydration; rasburicase optional for intermediate risk and recommended for high risk; allopurinol for those unable to receive rasburicase
Calcium ≤ 7 mg/dL (1.75 mmol/L) or > 25% ↓ from baseline	• Muscle cramp/spasms, tetany, paresthesia, neurologic (confusion, hallucination, seizure), arrhythmia, bradycardia, cardiac failure, death	• First, manage hyperphosphatemia • If symptomatic, IV calcium may be administered
Potassium ≥ 6 mEq/L (mmol/L) or > 25% ↑ from baseline	• GI (nausea, diarrhea, anorexia), muscle weakness/cramps, ECG abnormalities, sudden death	• Loop diuretic • IV insulin + dextrose • Inhaled albuterol • If mild/moderate – oral resin binder • If ECG changes – IV calcium • If acidotic – IV sodium bicarbonate
Phosphorous ≥ 4.5 mg/dL (1.45 mmol/L) in adults or ≥ 6.5 mg/dL (2.1 mmol/L) in children (> 25% ↑ from baseline)	• GI (nausea, diarrhea), lethargy, seizures	• Reduce phosphorus intake • Phosphorus binders

[a] Two or more of the laboratory changes must be observed within 3 days before or 7 days after cytotoxic therapy.

Data from References 17,73.

TLS Monitoring

TLS Monitoring includes laboratory markers (uric acid, potassium, calcium, phosphorus), renal function, urine output, fluid status, and if needed assessment for arrhythmias (electrocardiogram [ECG]) or seizure activity (electroencephalogram [EEG]). At a minimum, daily assessment during period of risk is required, but more frequent monitoring may be warranted. For example, patients with intermediate risk warrant monitoring every 8 to 12 hours while those classified as high risk and those with active laboratory or clinical TLS may warrant up to every 4- to 8-hour laboratory monitoring.[21] Further, certain cytotoxic therapies have specific guidance regarding required monitoring and management of TLS for patients receiving those agents (eg, venetoclax).[22]

Clinicians should consider trends in laboratory markers (ie, levels and time between any changes in levels), patient risk stratification, and time point around chemotherapy when making recommendations for monitoring and interventions. Adjustment of laboratory monitoring should occur based on patient response to interventions (ie, increase monitoring if optimal response not achieved, reduce frequency of monitoring if not TLS occurring).

Cessation of laboratory monitoring can occur once a patient is outside the period of risk, and all laboratory markers have been stable within normal limits at the discretion of the provider.

TLS Management

Prevention of TLS is paramount. First, in some high-risk patients, the oncologist may opt to "de-bulk" prior to initiating intensive cytotoxic chemotherapy to reduce the risk of severe TLS often with agents, such as cyclophosphamide or hydroxyurea.[23] Second, all patients should be risk stratified, which dictates prophylaxis. Overlap exists between prevention and management of TLS as all patients require ongoing monitoring and adequate hydration (Table 150-2).

Hydration is a mainstay in the prevention of TLS as it enhances urinary excretion of intracellular components via increased intravascular volume and improved renal perfusion enhancing glomerular filtration.[24] Guidelines recommend hydration with approximately 3 L/m^2/day for adult patients at intermediate-to-high risk of TLS[25] while others recommend fluid intake of one to two times maintenance requirements with a goal urine output of 80 to 100 mL/m^2/hr.[24] Although specific fluid types or hydration rates are not standardized, typical fluids are isotonic saline or dextrose containing product as potassium additives or fluids containing potassium (ie, Lactated Ringer's) should be avoided given the risk of hyperkalemia.[25] While diuretics may be used to enhance excretion, caution is warranted, and providers must first ensure no obstruction or hypovolemia exists. No benefit is seen with the addition of alkalinization (ie, sodium bicarbonate); therefore, this strategy is no longer recommended.[25] Hydration should be continued during management of TLS.

Prevention and Management of Hyperuricemia

Hyperuricemia occurs due to the breakdown of nucleic acids released from cells. As uric acid is poorly soluble, it can precipitate leading to obstructive uropathy and acute kidney injury. To prevent and manage hyperuricemia, patients at low risk may receive allopurinol, those with intermediate risk can receive either allopurinol or rasburicase, and those at high risk are recommended to receive rasburicase.

Allopurinol is a xanthine oxidase inhibitor which prevents the conversion of xanthine to uric acid. Therefore, this intervention is preventative with a slow onset of action and should ideally be initiated at least a day before starting chemotherapy. Notably, xanthine itself can accumulate and lead to crystallization, although the precise impact on TLS is not well characterized. Recommended dose of allopurinol is 300 mg/m^2/day PO in one to three divided doses rounded to tablet size (available in 100 mg and 300 mg tablets), with a maximum of 800 mg/day; intravenous (IV) administration is available with different dosing for those unable to take oral medications. Renal dose adjustment is necessary. Allopurinol may cause GI ADRs, rash, as well as hypersensitivity reactions particularly in Asian populations due to a higher frequency of HLA-B*58:01 allele associated with more severe cutaneous drug reaction.[19] Febuxostat is another xanthine oxidase inhibitor which may be used as an alternative to allopurinol.[26] This agent does not require renal dose adjustment and is associated with lower risk of hypersensitivity reactions.

In patients with hyperuricemia before anticancer treatment begins, xanthine oxidase inhibitors are unlikely to be effective. Therefore, rasburicase, a recombinant urate oxidase that converts uric acid into more soluble allantoin, is warranted for the management of hyperuricemia. A fixed-dose of rasburicase (6 mg IV once)[27] is recommended for adult patients as a cost-saving measure. Pediatric protocols may require weight-based dosing. Peak activity occurs around 4 hours, and it is generally well tolerated, although GI ADRs, headache, and rash may occur. Notably, pregnant patients and those with glucose-6-phosphate dehydrogenase (G6PD), deficiency are at risk for hemolysis and methemoglobinemia; therefore, assessment in those of certain ethnic background (African American, Mediterranean, or Southeast Asian) who are more likely to exhibit G6PD deficiency is warranted before administration if feasible. Further, blood samples drawn after administration of rasburicase must be immediately placed on ice for transport to laboratory, otherwise the drug continues to act on the blood sample and can lead to false low readings.

Management of Electrolyte Disturbances

Rapid treatment of hyperkalemia can be achieved with loop diuretics or intracellular shift of potassium via the administration of 10 units of IV insulin (0.1 unit/kg for pediatric patients) followed by dextrose (generally 25-50 mL of 50% dextrose for adults) or inhalation of albuterol. For mild hyperkalemia not necessitating rapid onset, cation exchange resins, such as sodium polystyrene sulfate 15 to 30 g PO once, with repeat doses as needed based on repeat potassium levels, can be utilized to remove potassium through the GI tract. Slow infusion of calcium gluconate (1 g IV for adults) can be administered to patients with ECG changes as it can stabilize myocardial membranes, while sodium bicarbonate (50 mEq IV for adults) can be administered if metabolic acidosis is present. Potassium level of 7 mEq/L (mmol/L) or greater or a widening QRS complex warrants immediate attention with aggressive interventions and close monitoring.[19]

Treatment of hyperphosphatemia includes minimization of dietary phosphorus intake and use of phosphorus binders (ie, sevelamer, calcium acetate, aluminum hydroxide), although caution is warranted for aluminum-based products in patients with renal dysfunction while calcium carbonate products should be avoided in those with hypercalcemia.

Hypocalcemia should not be directly managed unless the patient is symptomatic, due to the risk of furthering the calcium phosphate deposition in renal tubules. First, hyperphosphatemia should be corrected. If hypocalcemia is symptomatic, a slow infusion of calcium gluconate may be administered with ECG monitoring for resolution of symptoms and not necessarily correction to normal value.

Patients with congestive heart failure (HF), renal insufficiency (eg, anuria), calcium-phosphorus product of 70 mg^2/dL^2 (5.6 $mmol^2/L^2$)or more, or TLS refractory to aforementioned interventions may need dialysis to manage electrolyte disturbances.[19] Further details on electrolyte management can be found in Chapter 69, “Calcium and Phosphorous Homeostasis” and Chapter 70, “Potassium and Magnesium Homeostasis.”

Extravasation

Extravasation is the unintentional leakage of drug from the injection site into surrounding subcutaneous or subdermal healthy tissue where uptake of the drug may result in cell death. Symptoms and signs of extravasation may include pain, redness, or swelling as well as difficulty with the utilization of the IV line such as resistance to infusion or lack of blood return.[28] While fairly infrequent (incidence <7%), it can lead to negative patient outcomes and morbidity.[29] Prevention methods include but are not limited to proper vascular access, the use of central IV line (eg, port, peripherally inserted central catheter, also known as PICC), and adherence to chemotherapy administration guidelines.[30] Cytotoxic chemotherapy can be classified as exfoliants (cause tissue peeling/inflammation without cell death), inflammitants (cause inflammation/erythema/flare reaction without pain), irritants (cause inflammation/pain without tissue damage), or vesicants (cause tissue necrosis/blisters).[30]

Management of extravasation of a vesicant is specific to the chemotherapy agent and may include administration of a certain antidote (Table 150-3). Dimethyl sulfoxide administered topically neutralizes free radicals and promotes absorption as well as possesses anti-inflammatory, anesthetic, and vasodilatory properties. Hyaluronidase administered subcutaneously (SQ) promotes drug diffusion and absorption by degrading hyaluronic acid, which breaks down subcutaneous tissue bonds. Sodium thiosulfate administered SQ can neutralize mechlorethamine into nontoxic thioesters and neutralizes via the creation of an alkaline-rich environment where the vesicant can bind sodium thiosulfate.[28,30] Dexrazoxane is an IV agent, Food and Drug Administration (FDA) approved for the management of extravasation of anthracyclines due to its proposed mechanism of preventing free radical formation through binding of iron and reduction in oxidative stress. Precise dosing and administration information for each antidote agent can be found in product labeling and tertiary drug information resources.

TABLE 150-3

Management of Extravasation

Chemotherapy Agent/Vesicant	Potential Antidote(s)	Compress Recommendation	
		Cool	Warm
Anthracycline Agents	Dexrazoxane	X	
	Dimethyl sulfoxide		
Cisplatin	Sodium thiosulfate	X	
	Dimethyl sulfoxide		
Antitumor antibiotics			
Dactinomycin	--	X	
Mitomycin	Dimethyl sulfoxide	X	
Mitoxantrone	Dimethyl sulfoxide	X	
Docetaxel	Hyaluronidase	X	
Mechlorethamine	Sodium thiosulfate	--	--
Oxaliplatin	Sodium thiosulfate	Controversial/unknown	
Paclitaxel	Hyaluronidase	X	
Vinca Alkaloids	Hyaluronidase	Avoid	X

Data from References 28,30.

Nonpharmacologic interventions are standard for any extravasation and include immediate cessation of the chemotherapy agent, aspiration, avoidance of flushing line as this may further potentiate the extravasation, and elevation of the limb for ~48 hours to promote drainage.[28,30] Compresses generally applied for ~20 minutes four times a day for 24 to 48 hours are recommended. While a cool compress is recommended for extravasation of most agents to localize the vesicant by providing vasoconstriction to avoid further spread of the drug, only warm compresses should be used for the extravasation of vinca to avoid further tissue damage and promote drug absorption and redistribution.[28,30] Moist compresses and occlusive dressings should be avoided.[31]

IMMUNE-RELATED ADVERSE EVENTS

The use of ICIs (ie, cytotoxic T-lymphocyte-associated protein 4 [CTLA4], programmed cell death protein 1 [PD-1], and programmed death-ligand 1 [PD-L1] inhibitors) in cancer care has exploded at a rapid pace. These agents work by activating the immune system, but ICIs can also attack healthy cells causing a unique group of toxicities called irAEs. Although irAEs are the most notable toxicities seen with ICIs, fatigue is the most common ADR. The most commonly affected organ systems are skin, gut, endocrine, lung, and musculoskeletal system, whereas cardiovascular, hematologic, renal, neurologic, and ocular irAEs are rare. The onset of irAEs is delayed and varies by organ systemic affected and specific ICI administered. Rash/dermatitis presents first, about 2 to 3 weeks following first ICI dose, while diarrhea/colitis typically presents around week 5, and hepatotoxicity and hypophysitis around week 7.[32] The incidence rate of any grade irAEs ranges from 15% to 90%.[1] CTLA4 inhibitors are associated with a higher rate of irAEs than PD-1/PD-L1 inhibitors, and severe irAEs result in treatment delay or discontinuation in 0.5% to 13% of patients. Combination treatment of ipilimumab and nivolumab is associated with the highest rate of severe irAEs and often requires treatment delay or discontinuation. Fortunately, irAEs are typically reversible, with the exception of endocrine-related irAEs.

The prompt recognition and management of irAEs is key to keeping patients on therapy. Several clinical practice guidelines to manage irAEs have been published by various professional organizations including the Society for Immunotherapy of Cancer,[33] the European Society for Medical Oncology,[34] the NCCN,[1] and ASCO.[32] The majority of irAEs that occur are mild to moderate, and patients may typically continue on ICI therapy. Notably, ICI therapy is not dose-reduced for toxicities, only held/delayed. Management varies slightly by the organ system affected, but first-line therapy is commonly systemic corticosteroids with doses ranging from 0.5 to 2 mg/kg/day of oral prednisone. If corticosteroids are indicated for irAE management, ICI therapy should be held until the irAE is grade ≤ 1 and the patient has tapered off corticosteroids. Patients who present with severe irAEs are treated with IV methylprednisolone at 1 to 2 mg/kg/day initially and typically require ICIs to be held or permanently discontinued. If no response to corticosteroids within 48 to 72 hours, additional immunosuppression is recommended based on evidence for treating autoimmune diseases for the respective organ system affected. Commonly employed immunosuppressive agents include tumor necrosis factor (TNF) inhibitors (ie, infliximab, etanercept), vedolizumab, mycophenolate, IV immunoglobulin, or IVIG, and rituximab.

Patients on prolonged corticosteroid require additional interventions, including monitoring for hyperglycemia, H2-receptor antagonists, or proton pump inhibitors to prevent gastritis and anti-infective prophylaxis (eg, consider prophylaxis against herpes zoster), and vitamin D and calcium supplementation (see "Bone Health" section). Patients receiving prednisone equivalent of ≥20 mg for ≥4 weeks require PJP (*Pneumocystis jirovecci pneumonia)* prophylaxis as well as fungal prophylaxis (eg, fluconazole) if it is continued for ≥6 weeks. In patients requiring anti-TNF therapy, testing for hepatitis B and C virus should be conducted prior to administration if possible, but should not delay initiation of TNF inhibitor treatment. TNF inhibitors should be avoided in patients with immune-related hepatitis due to the risk for hepatotoxicity.

Patients at higher risk of developing irAEs or experiencing an exacerbation of underlying comorbidities include those with autoimmune diseases. These patients may experience a flare of their underlying condition; therefore, immunosuppression for their pre-existing autoimmune condition should be optimized prior to ICI initiation. Ideally, patients who are on prednisone for their autoimmune condition would be controlled on <10 mg of prednisone daily (or equivalent) prior to starting ICI. Caution is also utilized in patients who were prior organ transplant recipients as they are at risk for graft failure and transplant organ loss. In patients who received an allogeneic stem cell transplant, graft-versus-host disease (GVHD) is a risk.

ICIs are a significant advancement in the treatment of cancer; however, they are associated with unique toxicities called irAEs. These toxicities are delayed in presentation and have a prolonged duration. irAEs may occur months and even years after ICI discontinuation requiring clinicians to remain vigilant in monitoring patients. irAEs are commonly managed with immunosuppression, typically corticosteroids. Patients with mild-to-moderate irAEs can often remain on therapy, but patients who require corticosteroids or have severe irAEs often need to have treatment held or permanently discontinued. Additional supportive care interventions are required in patients on prolonged courses of corticosteroids or who require additional immunosuppressive therapy beyond corticosteroids.

CELLULAR IMMUNOTHERAPY ADRs: CRS AND NEUROTOXICITY

While immune activation directly leads to the efficacy of therapies that engage T cells, the subsequent massive release of various cytokines can lead to clinically significant ADRs, namely CRS and neurotoxicity. These events can occur after infusions of any cellular immunotherapy product, such as CAR-T therapy (eg, tisagenlecleucel and axicabtagene ciloleucel) or bispecific T-cell engaging therapy (BiTE; eg, blinatumomab). These ADRs require prompt identification and accurate grading to provide optimal management. However, their grading and management may differ by product as delineated below. Ongoing studies are evaluating optimal prevention and management of these ADRs.

CAR-T

CRS is caused by endogenous or infused immune effector cells, such as T cells, leading to a supraphysiologic and rapid release of cytokines.[35] CRS grading is based on symptoms, which includes fever at onset and may also include hypotension and/or hypoxia.[35] Symptoms can be progressive, and end-organ damage may occur. CRS typically presents in the first 2 weeks with median onset of approximately 3 days after CAR-T infusion and median duration of about 1 week necessitating monitoring of vital signs (temperature, BP, and oxygen saturation) twice daily during this time.[1] Treatment of CRS includes antipyretics for fever with fluid and/or oxygen supplementation as clinically necessary. Tocilizumab, an anti-interleukin-6 agent, is FDA approved for moderate to severe cases (eg, grade 2 and higher CRS) dosed as 8 mg/kg IV (maximum dose: 800 mg) with up to three repeat doses in 24 hours. Dexamethasone 10 mg IV up to every 6 hours is recommended for persistent refractory grade 2 (eg, nonresponse to 1-2 doses of tocilizumab) and for grade 3-4 CRS. For refractory grade 4, methylprednisolone 1,000 mg/day for up to three doses IV can be utilized with escalation to every 12 hours if refractory.[1,36]

Neurotoxicity after cellular immunotherapy was specifically termed immune effector cell-associated neurotoxicity syndrome (ICANS).[35] ICANS is thought to be due to diffusion of either the immune effector cells and/or cytokines through blood brain barrier into the CNS. ICANS typically occurs within the first 4 weeks of cellular infusion with median onset of approximately 7 days and duration of about 14 days.[1] Signs and symptoms of ICANS can vary among patients and may include aphasia, impairment in cognition, reduced level of consciousness, seizures, motor weakness, or cerebral edema. ICANS Grading requires the assessment of five domains: level of consciousness, seizure activity, motor findings, cerebral edema/elevated intracranial pressure, as well as the ten-point Immune Effector Cell-Associated Encephalopathy, or ICE Score, which should all be assessed twice daily during the at-risk period.[1] Notably, the Cornell Assessment of Pediatric Delirium (CAPD), is used instead of ICE Score for pediatric patients under the age of 12 years with further specific guidance available for interpreting actions in patients under 2 years.[35] Management of ICANS includes supportive care with aspiration precautions as well as anti-epileptics and interventions to manage elevated intracranial pressure as needed. Further, corticosteroids are the mainstay of management of ICANS of Grade 2 or higher[36] with dexamethasone (grade 2: 10 mg IV and may repeat; grade 3: 10 mg IV q 6 hour or methylprednisolone 1 mg/kg IV q12 hour; grade 4: high-dose steroid regimen such as methylprednisolone 1,000 mg/day or twice daily × 3 days with a rapid taper over approximately 1 week).[1]

Bispecific T-Cell Engaging (BiTE)—Blinatumomab

Blinatumomab is a BiTE antibody construct that links CD3 T cells to the targeted malignant cells (CD19 B cells) for destruction in patients with B-cell acute lymphoblastic leukemia, or ALL. Unlike CAR-T therapy, which once infused is active within the body, due to short half-life blinatumomab is administered as a continuous infusion which allows for the management of ADRs via holding dose or discontinuation.

CRS is less common and often less severe after blinatumomab than CAR-T, most often low grade and occurring in first cycle or at dose escalation.[37,38] Prevention of CRS includes cytoreduction for high-risk patients, initiation of blinatumomab with dose escalation inpatient for monitoring, and routine prophylactic dexamethasone.[38,39] The CTCAE is utilized for grading CRS after blinatumomab. Management of CRS from blinatumomab includes utilization of dexamethasone, dose interruption, or discontinuation[38] and potentially off-label use of tocilizumab for severe CRS.[37] Notably, the use of corticosteroids has not been shown to impact efficacy.[40]

Neurotologic events are common after blinatumomab (~50%-65% of patients), most frequently occurring within 1 to 2 weeks of the first cycle.[37] Severe (Grade 3 or higher) events occur in approximately 10% to 20% of patients which necessitates holding therapy and resumption at a lower rate with permanent discontinuation for Grade 4 neurotoxicity, if >1 seizure, or if recurs when a patient is receiving reduced infusion rate.[38] Precise management may vary by institution or research protocol,[41] including the use of dexamethasone or tocilizumab for severe symptoms (encephalopathy, aphasia).[37,39,41] Anti-epileptics are warranted for patients with seizure activity, although prophylaxis is not routinely utilized.[39]

DERMATOLOGIC TOXICITIES

Anticancer treatment can cause a variety of dermatologic toxicities affecting a patient's skin, hair, and nails. These toxicities may result in dose reductions or treatment discontinuation, which affects patient outcomes. It is important to be able to accurately recognize, prevent, and manage these ADRs.

Skin

Dry Skin (Xerosis) and Pruritus[42–44]

Dry skin is reported in up to 84% of patients on anticancer treatment and can negatively impact their quality of life and lead to infections, sensitization to allergens and pruritus. Dry skin and pruritus are reported more commonly with targeted therapies. Skin can be more sensitive to ultraviolet radiation and more prone to skin pigmentation. Counseling points on prevention measures include avoiding alcohol-containing lotions and irritating products, limiting shower time, using gentle cleansers, routinely applying emollients and sun-protective measures. Treatment of mild-to-moderate pruritis can include a topical antipruritic agent containing menthol 0.5% or a topical corticosteroid (mometasone furoate 0.1% ointment or betamethasone valerate 0.1% ointment) and oral antihistamines, in particular nonsedating second-generation agents. Second-line options include antiepileptic agents (pregabalin and gabapentin), doxepin, aprepitant, and short-term, systemic corticosteroids (0.5-2 mg/kg/day).

Acneiform RASH[43]

Acneiform rash or papulopustular eruption is characterized by an eruption of papules and pustules commonly appearing on the face, scalp, upper chest, and back. It is the most common ADR in patients treated with EGFR inhibitors (all grade: 75%-90%, grade 3/4: 10%-20%) and commonly seen in patients on MEK (mitogen-activated protein kinase) inhibitors (all grade: 74%-85%, grade 3/4: 5%-10%). It begins within the first few days to weeks following treatment initiation, and patients report pruritus, stinging, and pain. Prevention and management strategies for this rash are detailed in Table 150-4 and commonly include a good skin care routine, avoidance of sun exposure, topical corticosteroids, and oral antibiotics.

TABLE 150-4

Acneiform Rash/HFS/HFSR

Toxicity	Prevention	Treatment
Acneiform rash (Papulopustular Exanthema)	• Avoid frequent washing with hot water • Avoid skin irritants, including OTC anti-acne medications containing benzoyl peroxide, solvents, or disinfectants • Use alcohol-free[a] OTC moisturizing creams or ointments BID, preferably with urea-containing (5%-10%) moisturizers to the body • Avoid excessive sun exposure • Apply sunscreen (SPF) ≥15 to exposed areas of body and reapply every 2 hours when outside • Oral antibiotics for 6 weeks at start of therapy (doxycycline 100 mg PO BID or minocycline 100 mg PO daily; if unable to tolerate/allergy cephadroxil 500 mg PO BID or trimethoprim-sulfamethoxazole 160/80 mg PO BID), with or without topical low/moderate-strength steroid to face and chest BID	Grade 1/2: ○ Continue anticancer treatment ○ Continue or initiate: oral antibiotic for 6 weeks AND topical low/moderate steroid ○ Reassess after 2 weeks; if no improvement or worsening escalate therapy Grade ≥ 3: ○ Interrupt anticancer treatment until grade 0/1 ○ Obtain bacterial/viral/fungal cultures if infection is suspected ○ Continue or initiate: oral antibiotic for 6 weeks AND topical low/moderate steroid, systemic corticosteroids (eg, prednisone 0.5-1 mg/kg × 7 days) ○ Reassess after 2 weeks; if no improvement or worsening may need to discontinue treatment
HFS and HFSR	• Avoid irritation to hands and feet; long walks, heavy carrying without protection • Avoid chemical stress; skin irritants, solvents, or disinfectants • Treat predisposing factors before anticancer therapy • Apply 10% urea cream TID • For taxane-based therapy: use skin cooling gloves or socks • For capecitabine-based therapy: may consider celecoxib 200 mg PO BID	• Anticancer treatment interruption and dose reduction commonly required; initiation of topical agents (HFS and HFSR) or cooling (HFS) may allow for continued dosing • Hyperkeratosis: treat with keratolytics (topical creams or ointments with 5%-10% salicylic acid or 10%-40% urea) • Inflammation: high-potency topical corticosteroids (eg, clobetasol proprionate 0.05%) • Erosions and ulcerations: antiseptic solutions (eg, silver sulfadiazine 1%, polyhexanide 0.02%-0.04%) • Pain: lidocaine 5% cream or patches • Reassess after 2 weeks; if no improvement or worsening escalate therapy

BID, two times daily; OTC, over the counter; SPF, sun protection factor; TID, three times daily

[a] Avoid SD alcohol 40, denatured alcohol, ethanol, and isopropyl alcohol.

Data from Reference 43.

Hand-Foot Syndrome and Hand-Foot Skin Reaction[43]

Hand-foot syndrome (HFS) also known as palmar-plantar erythrodysesthesia syndrome, acral erythema, or toxic erythema, is characterized by redness, marked discomfort, swelling, and tingling in the palms of the hands and soles of the feet. Common chemotherapy causes include 5-fluorouracil, capecitabine, doxorubicin, pegylated liposomal doxorubicin, docetaxel, and cytarabine. It may be severe (grade 3/4) in 5% to 10% of patients, and the incidence increases with the use of multiple causative agents. Hand-foot skin reaction (HFSR) differs from HFS in presentation with well-defined painful hyperkeratosis. Multikinase VEGFR inhibitors such as sorafenib, cabozantinib, sunitinib, and regorafenib are a common cause. HFSR is less common with lenvatinib, pazopanib, and sunitinib and is grade 3/4 in 5% to 20% of patients.

The onset of this reaction is usually within days to weeks, but may take up to 6 months to appear. With HFS, the first symptoms are dysesthesia of the palms and soles with a tingling that develops into burning pain, swelling, and erythema followed by hyperkeratosis. Lesions can progress to blisters, desquamation, erosions, ulcerations, and bleeding associated with discomfort and moderate to severe pain. HFSR more commonly affects the soles and blisters occur followed by callus-like hyperkeratosis at pressure-bearing areas. Table 150-4 includes prevention and management strategies for HFS and HFSR.

Pigmentary Changes[42]

Hyperpigmentation may occur at different sites and in different patterns. It can present within days to months after treatment and usually fades months after therapy discontinuation. Some of the agents associated with hyperpigmentation include busulfan, bleomycin, methotrexate, capecitabine, 5-fluourouracil, docetaxel, doxorubicin, ifosfamide, and thiotepa. C-kit inhibitors (eg, imatinib) can cause diffuse or localized hypopigmentation, as c-kit is involved in the regulation of melanocyte function. It is usually reversible with dose reductions or discontinuation. Patients, especially those with melanoma, on immunotherapy may experience vitiligo-like lesions.

Other Rashes[42]

Many treatments may cause a nonspecific maculopapular rash or morbilliform eruption that starts gradually with mild symptoms including pruritus weeks after treatment.[42] Management includes antihistamines and when localized topical corticosteroids or when more diffuse short-term oral corticosteroids. Up to 50% of patients on rapidly accelerated fibrosarcoma (RAF), v-raf murine sarcoma viral oncogene homolog B1 (BRAF) inhibitors may experience a maculopapular rash that appears early and spreads quickly.[45] Approximately 20% of patients on these therapies also develop nonmelanoma skin cancer that should be excised. Less commonly, rash occurs in patients treated with gemcitabine, pemetrexed, and liposomal doxorubicin.[45] Up to 95% of patients may experience acute or chronic RT dermatitis, and patients receiving concurrent chemotherapy are at higher risk.[46] A delayed recall reaction may occur weeks to years following RT and present as a new rash that appears after treatment with a precipitating drug. Common offending agents include taxanes, doxorubicin, and gemcitabine. Prevention and management strategies include instructing the patient to wear loose fitting clothing to avoid friction, avoid sun exposure and exposure to extremes of temperature, and not use cosmetic or irritating products to the radiated skin. Patients should use a good emollient during treatment, and topical corticosteroids may be added. Anticancer treatment can cause photosensitivity, phototoxic, or photoallergic reactions. Inflammatory rashes occur on photo-exposed areas in patients treated with 5-fluorouracil and taxanes. Vemurafenib and vandetanib are associated with ultraviolet A (UVA), sensitivity, and preventive sun measures are required.[42]

Hair

Alopecia[42,43]

Alopecia is one of the more distressing and well-known dermatologic toxicities mainly caused by chemotherapy but is also reported with targeted agents and hormone therapy. Chemotherapy-induced alopecia (CIA) typically results in diffuse complete hair loss on the entire scalp, but patients may have diffuse partial alopecia, or patchy, unevenly distributed alopecia. It may also involve eyebrows, eyelashes, and body hair. CIA typically begins 1 to 3 weeks after treatment, and hair will start regrowing 2 to 3 months after completion. Hair loss severity is dependent upon the type, dose, method of administration, and time between treatments. Cyclophosphamide, doxorubicin, irinotecan, and taxanes are associated with a high risk of CIA.

Endocrine therapy-induced alopecia usually does not result in complete hair loss and is located primarily on the crown of the scalp, with the recession of the frontal and bitemporal hairline. It is more common in postmenopausal women receiving aromatase inhibitors and is most noticeable between 6 and 18 months after treatment initiation. Scalp cooling is the only proven method to prevent CIA, but efficacy is only 50% to 80%. Scalp cooling causes vasoconstriction and reduced biochemical activity in the scalp and hair follicles. These techniques are contraindicated in patients whose cancer can metastasize to the scalp, such as leukemia and lymphoma. To treat alopecia following anticancer treatment, patients may use topical minoxidil 5%. Patients may also consider taking biotin to stimulate hair growth. Patients are informed about the potential alopecia prior to initiating treatment, and a discussion regarding hats, scarfs, or wigs to protect the scalp should occur.

Other Hair Changes[42]

Patients on targeted therapies may report changes in hair quality, texture, and growth pattern starting months 2 or 3 of treatment. Excessive hair growth in androgen-dependent areas of the body may occur in women on endocrine therapies. Trichomegaly, or longer, thicker, and often curled eyelashes and hypertrichosis are associated with EGFR inhibitors. Patients may need to trim their eyelashes to prevent eye irritation. The hypopigmentation associated with c-KIT inhibitors, such as pazopanib, also impacts the hair presenting as white hair growth.

Nails

Nail changes are common during treatment and usually disappear following the completion of therapy.[42] Cytotoxic chemotherapy usually results in melanonychia (black or brown discoloration that is diffuse, transverse, or longitudinal), leukonychia (white spots), onycholysis (nail detachment from the nail bed), Beau's lines (indentations across the nail), onychomadesis (proximal separation of the nail plate from the nail matrix), and onychorrhexis (brittle nails). Patients receiving a taxane may experience painful subungual hemorrhage followed by onycholysis and occasional abscess. Chemotherapy and targeted therapy may cause brittle nails, nail cracking, and splitting. Preventive strategies include decreased exposure to water, use of cotton gloves, and nail hydration with thick emollients. Patients may consider oral biotin to help with nail growth and nail lacquers. Asymptomatic splinter subungual hemorrhages of black, red, or brown are common in patients treated with VEGFR inhibitors. EGFR inhibitors are associated with the risk of paronychia occurring two or more months after treatment initiation on finger and toenails. Similar lesions are reported less frequently with MEK inhibitors and mTOR inhibitors.[43] Additional prevention methods include the use of comfortable shoes, adequate nail trimming, and use of antiseptic solutions. If fissuring occurs, protective covering should be applied.

ENDOCRINE TOXICITIES

The endocrine system is complex and composed of a series of glands that produce and secrete hormones used by the body for a variety of functions. Anticancer treatment can impact these glands resulting in dysfunction in hormone production.

Hypothalamic-Pituitary Dysfunction

RT is a common cause of hypothalamic-pituitary dysfunction in patients with cancer. The onset and severity are dose-dependent and may occur years later. Symptoms are nonspecific and include fatigue and weakness. Management includes hormone replacement as necessary.[47] Although rare, ICI can cause hypophysitis, inflammation of the pituitary gland which is delayed in onset and also managed with hormone replacement as well as ICI dose delays and discontinuation if necessary[1] (see Chapter e98, "Pituitary Gland Disorders").

Thyroid Dysfunction

Thyroid function can be affected by a variety of anticancer treatments including RT, targeted therapy, and cytokines.[48] Hypothyroidism is more common than hyperthyroidism. Patients on multitargeted TKIs and ICIs should have their thyroid function (thyroid-stimulating hormone [TSH] and free thyroxine or T4) monitored at baseline and periodically while on treatment. Hypothyroidism is common in patients on sunitinib, with a variable onset, most commonly 4 weeks. Other TKIs associated with hypothyroidism include sorafenib, imatinib, dasatinib, nilotinib, and axitinib. Drug-induced hypothyroidism can persist following TKI discontinuation. Patients on thyroid hormones prior to treatment initiation often need dose increases while on TKI treatment. ICIs are associated with both hyper- and hypothyroidism, with hypothyroidism being more common. Hyperthyroidism also often transitions into hypothyroidism. Patients can typically continue on ICI but need lifelong thyroid supplementation.[1] RT to the neck is associated with primary hypothyroidism, especially when treated during childhood. Five years after treatment nearly half of patients develop hypothyroidism, with a median onset of 1.5 years posttreatment[48] (see Chapter 96, “Thyroid Disorders”).

Hyperglycemia

Hyperglycemia is a common toxicity seen in patients with cancer. Glucocorticoids are likely the most common cause of hyperglycemia. They are used as an antiemetic, for edema from brain metastasis, prevention of transplant rejection, treatment of GVHD, and irAEs, and even in some anticancer treatment regimens.[49] Agents that inhibit the phosphoinositide-3 kinase (PI3k)/protein kinase B (also known as AKT)/mTOR pathway are associated with hyperglycemia due to the interruption of intracellular response to insulin, resulting in decreased glucose transport, decreased glycogen synthesis, and increased glycolysis.[50] The PI3K inhibitors (eg, alpelisib) and mTOR inhibitors (eg, everolimus) are associated with grade 3 to 4 hyperglycemia in approximately 10% of patients. ICIs can rarely cause hyperglycemia, pancreatitis, and new-onset type I diabetes. L-asparaginase can induce hyperglycemia through both direct and indirect effects and inhibit insulin production and release and pancreatitis, respectively.[49]

Patients should be periodically screened for diabetes by fasting plasma glucose, oral glucose test, hemoglobin A1c, random plasma glucose levels, or pre- or postprandial glucose testing. Management of hyperglycemia should consider glycemic variability of the agent administered, and commonly includes oral anti-hyperglycemic agents and insulin. Patients may require treatment interruption or discontinuation if hyperglycemia cannot be controlled[49,50] (see Chapter 94, “Diabetes Mellitus”).

BONE HEALTH

Cancer and its treatment can have a significant impact on bone health. Patients may be at risk for osteoporosis and metastatic bone disease, which can significantly affect quality of life.

Osteoporosis

Osteoporosis is a common complication of anticancer treatment, especially hormonal therapy.[51] Additionally, chronic inflammation associated with cancer can promote increased bone loss via altered systemic bone remodeling, increased bone resorption, and impaired bone formation. Rates of bone loss from anticancer treatment can be more than seven-fold greater than that of normal aging. Patients with the following conditions may be considered for bone-modifying treatment: premenopausal women receiving gonadotropin-releasing hormone (GnRH) therapies causing ovarian suppression, premenopausal women with chemotherapy-induced ovarian failure or who have had an oophorectomy, postmenopausal women who are receiving aromatase inhibitors, men who have received or are receiving androgen deprivation therapy, patients undergoing or with a history of bone marrow transplantation, or patients with chronic (>3-6 months) glucocorticoid treatment. Assessment and treatment of bone loss is similar to other patients at risk for osteoporosis (see Chapter 112, “Osteoporosis” for more detail).

Bone Metastases

Metastatic bone disease is common in multiple myeloma, prostate, breast, lung, and kidney cancer.[52] Bone metastases commonly affect the axial skeleton and lead to skeletal-related events (SREs): pathological fracture, need for RT to the bone, surgery to bone, spinal cord compression, and hypercalcemia of malignancy. Bone pain is the result of structural damage and will be discussed in more detail (see “Bone Pain (Not Oncologic Emergency)” section). Preventing SREs is important as they are associated with loss of mobility, decreased social functioning, reduced quality of life, increased health care expenditure, and poor survival.

The pathophysiology of bone metastases is not completely understood.[52] Disseminated tumor cells enter the bone marrow microenvironment and may stay dormant for years before causing damage. Proliferating tumor cells can produce a variety of cytokines and growth factors, which increase osteoblast production of receptor activator of nuclear factor kappa-B ligand, or RANKL, that then leads to the activation of osteoclasts and disruption of normal bone formation and bone resorption. Multiple skeletal sites are typically involved. Patients report pain and boney tenderness. Imaging modalities (eg, computed tomography [CT] scan, magnetic resonance imaging [MRI], bone scan, positron emission tomography [PET]) are used for diagnosis and monitoring every 3 to 6 months.

The goal of treatment is to prevent disease progression and palliate symptoms.[52] Treatment varies by the underlying malignancy. Local external beam RT is effective at relieving painful bone metastasis with overall response rates of 70% to 80%. Approximately one-third of patients report complete pain relief. Targeted RT with systemic radioisotopes may be used to spare normal tissues in patients will multiple metastatic sites in some malignancies. Radium-223 (^{223}Ra) is a bone-seeking alpha particle-emitting radiopharmaceutical approved for use in bone-predominant metastatic castration-resistant prostate cancer (see Chapter 154, "Prostate Cancer"). Surgical intervention may be recommended to maintain patient function and mobility by relieving pain, preventing impending fractures and/or neural compression, or stabilizing a pathological fracture.

Bone-modifying agents (BMA; eg, zoledronic acid, pamidronate, and denosumab; Table 150-5), potent inhibitors of bone resorption, are also used to relieve pain and reduce the risk of and time to the development of SREs. Patient factors including the risk for an SRE and overall disease control help to determine which BMA is used. Denosumab is preferred when considering efficacy, convenience, and renal health. However, generic bisphosphonates are more cost-effective and not associated with a risk of rebound osteolysis. Once a patient develops bone metastases, it is common to initiate therapy and continue indefinitely. Use in specific cancers will be discussed in their respective chapters (see Chapter 151, "Breast Cancer"; Chapter 154, "Prostate Cancer"; and Chapter 159, "Multiple Myeloma"). BMAs are generally well tolerated; however, they may cause hypocalcemia due to the inhibition of bone resorption. Calcium and vitamin D levels should be monitored at baseline and throughout treatment.[52,53] Patients who are vitamin D deficient should be repleted and then maintained with daily supplements of 800 to 2,000 units/day. To maintain an adequate daily calcium intake, supplementation of 1,000 to 1,200 mg/day should be recommended. With prolonged BMA administration, it is important to monitor for osteonecrosis of the jaw and for patients to have a thorough dental exam prior to initiation if possible.

TABLE 150-5

BMA Dosing for Bone Metastases

Medication	Brand Name[a]	Dose
Denosumab	Xgeva	120 mg SQ every 4 weeks
Pamidronate	Aredia	90 mg IV over 2 hours every 3-4 weeks
Zoledronic acid	Zometa	4 mg IV over 15 minutes every 3-4 weeks[b]

[a] Note: unique brand names, dosing, and schedule for this indication

[b] May be dosed every 12 weeks after treatment for 3-6 months

Data from Reference 52.

Spinal cord compression is a medical emergency that required an urgent MRI to confirm the diagnosis.[52] Patients with spinal cord compression should receive 16 to 24 mg of dexamethasone/day to decrease inflammation and preserve function. This should be tapered over 2 weeks if possible. Patients with a single are of compression and good performance status may be amenable to surgery followed by RT. Patients unable to tolerate surgery should receive RT alone.

OTHER TOXICITIES

Ocular Toxicities

A broad spectrum of ocular toxicities may be seen with anticancer treatment. Common ocular toxicities reported include blurred vision, photophobia, conjunctivitis, cataracts, abnormal lacrimation, dry eye, keratitis, optic neuropathy, and retinopathy.[54–56] Ocular toxicities are typically mild (grade 1-2) but may progress to severe and result in blindness. For agents associated with more severe toxicities, routine ophthalmic surveillance and baseline assessment are recommended. Follow-up appointments with the cancer care team should include an assessment of eye pain, redness, and changes in vision. Some specific management strategies for ocular toxicities include artificial tears and lubricants for dry eyes and keratitis, steroid eye drops for conjunctivitis (especially from high-dose cytarabine), and systemic diuretics to manage periorbital edema (that is common with BCR-ABL TKIs like imatinib). Patients who experience photophobia and flashing lights from anaplastic lymphoma kinase (ALK) inhibitors tend to have symptoms improve over time.

Cardiovascular Toxicities

Patient-related and treatment-related factors contribute to cardiovascular toxicities experienced by patients with cancer.[57] Cardiovascular toxicity may be a short- or long-term complication, asymptomatic or symptomatic, as well as reversible or irreversible. Patients may experience HF, HTN, QT prolongation, arrhythmias, myocarditis, and other cardiac abnormalities from systemic treatment, RT, CAR-T therapy, or HSCT. A thorough cardiac workup should be conducted before initiating any potential cardiotoxic treatment, and any conditions identified should be well controlled according to current cardiovascular guidelines before treatment. A baseline risk assessment should include cardiac history, anticancer treatment history, cardiovascular risk factors, BP, hemoglobin A1c, cholesterol profile, cardiac biomarkers (troponin and natriuretic peptides), ECG, and echocardiogram (ECHO).

Left Ventricular Dysfunction/Heart Failure

Anthracyclines, HER2-targeted therapy, VEGFR inhibitors, and some proteasome inhibitors (eg, carfilzomib) may cause left ventricular dysfunction (LVD).[58] Anthracyclines are associated with type I LVD, which is a result of cellular loss, and is irreversible.[59] Anthracycline-induced cardiotoxicity can be categorized as acute, occurring immediately after the infusion (<1% of patients); early-onset progressive, occurring during therapy or within the first year of treatment (~2%); or late-onset chronic, occurring at least 1 year after therapy (1.6%-5%). Risk factors include cumulative dose, IV bolus administration, higher single dose, history of prior RT, use of other concomitant cardiotoxic drugs (cyclophosphamide, trastuzumab, paclitaxel), female gender, underlying cardiovascular disease, age (young and older adult), increased time since completion of chemotherapy, and increase in cardiac biomarkers (troponin, natriuretic peptides) during and after treatment. The risk of cardiotoxicity is cumulative, whereby patients are at risk for cardiotoxicity when they have reached the cumulative lifetime doses of anthracyclines. Patients who have received more than one type of anthracycline should have their cumulative lifetime dose converted to doxorubicin equivalents. (Table 150-6).[60] Type II cardiotoxicity results from cellular dysfunction (mitochondrial and protein alterations) and is usually temporary, without injury marker release, and cardiac function returns to baseline. HER2-targeted agents and VEGF inhibitors are common examples of agents that cause type II LVD. When these agents are given in combination with anthracyclines, the risk of cardiovascular toxicity increases; therefore, trastuzumab should not be given in combination with anthracyclines. Type II LVD is not dose-related or cumulative.

TABLE 150-6

Lifetime Cumulative Anthracycline Dose Conversion and Maximums

Anthracycline	Conversion Factor	Maximum Recommended Cumulative Dose (mg/m^2)
Doxorubicin	1	550
Daunorubicin	1	550 (no CV risk factors)
	0.7	400 (chest irradiation or CV risk factors)
Epirubicin	1.6	900
Idarubicin	0.3	150
Mitoxantrone	0.25	140

CV, cardiovascular.

Data from Reference 60.

Quantitative assessment with an ECHO or multigated acquisition (MUGA) of LV ejection fraction (LVEF) and diastolic function prior to cardiotoxic treatment may help to identify patients at high risk of cardiovascular complications.[58] It also serves to establish a baseline should symptoms occur during treatment. Patients should have routine monitoring with an ECHO or MUGA while on therapy (for HER2 therapy every 3 months; for anthracyclines after cumulative doxorubicin dose of 250 mg/m^2 or its equivalent, or after each additional 100 mg/m^2) and following treatment completion to evaluate for delayed onset cardiovascular toxicity.

Patients receiving treatment known to cause cardiotoxicity should be considered to have stage A HF (see Chapter 36, "Chronic Heart Failure"). Patients may be considered for prophylactic angiotensin converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), or selected beta-blockers (BBs) to decrease the risk of cardiotoxicity. Dexrazoxane may be used as a cardioprotectant in certain patients receiving >300 mg/m^2 cumulative anthracycline-based treatment, or at anthracycline treatment initiation in patients with pre-existing cardiomyopathy. Because dexrazoxane has the potential to decrease anthracycline efficacy due to its free radical scavenging activity, and it is not widely used.

Asymptomatic patients treated with anthracyclines who have a decrease in LVEF of ≥10% (0.10)from baseline to 50% or a decrease to ≥40% (0.40) and <50% (0.50), initiation of cardioprotective agents (ACEIs, ARBs, or BBs), if not already prescribed, and a cardiology (cardio-oncology specialist) consultation should occur. A benefit-risk discussion for continued anthracycline use versus changing to nonanthracycline treatment should occur. Patients may benefit from the use of dexrazoxane or liposomal doxorubicin, if appropriate. Patients on trastuzumab who experience the same impact in LVEF should also have a cardiology consultation and cardioprotective treatments started. If mild asymptomatic reductions in LVEF occur trastuzumab therapy may be continued. If trastuzumab is stopped, LVEF can be reassessed within 3 to 6 weeks and restarted if LVEF is >50% (0.50). In patients on other therapy associated with LVD, if LVEF decreases, cardioprotective treatment and repeat LVEF assessment should occur every 3 months. Patients who have LVD and are diagnosed with HF should be managed according to the American College of Cardiology/American Heart Association guidelines.

Hypertension

HTN is a risk factor for chemotherapy-induced cardiotoxicity. Several cancer treatments are associated with the risk of HTN, most notably the VEGF inhibitors. BP increases usually occur within 1 day of treatment initiation and stabilizes within 6 to 10 days. Possible predictors of HTN include age ≥ 60 years, body mass index ≥ 25 kg/m^2, and pre-HTN. Resting BP should be monitored daily during the first cycle of VEGF inhibitor treatment, and once BPs are stabilized, it can be extended to every 2 to 3 weeks while on treatment. More frequent monitoring is recommended in patients with pre-existing HTN and those at a higher cardiac risk. Potential contributors to BP elevation include obstructive sleep apnea, excessive alcohol consumption, nonsteroidal anti-inflammatory drugs (NSAIDs), adrenal steroids, erythropoietin, oral contraceptives, and sympathomimetics (methylphenidate). Management of HTN should follow the American College of Cardiology/American Heart Association guidelines (see Chapter 30, "Hypertension"). It is important to be mindful of potential drug-anticancer treatment interactions when selecting antihypertensive therapy. Once VEGF inhibitor therapy is stopped, HTN management should be modified and stopping antihypertensive therapy may be necessary to avoid hypotension.

QT Prolongation

Several anticancer therapies have a known potential to cause QT prolongation including arsenic trioxide, midostaurin, histone deacetylase inhibitors, TKIs and cyclin-dependent kinase 4/6 inhibitors.[58] Some agents with warnings for serious or life-threatening risks for QT interval prolongation include sunitinib, sorafenib, vandetanib, crizotinib, vemurafenib, dasatinib, lapatinib, and nilotinib. Agents associated with QT interval prolongation should be used with caution in patients with hypokalemia or hypomagnesemia, genetic long QT syndrome, and those on other QT prolonging medications. Electrolyte abnormalities should be corrected prior to initiation and during therapy. ECGs should be conducted at baseline and periodically to assess for QT prolongation and arrhythmia.

Others

Atrial fibrillation (AF) can also occur with some anticancer agents (eg, ibrutinib, anthracyclines, immunomodulatory agents).[61] Management of AF from anticancer treatment considers rhythm versus rate control and thromboembolic prophylaxis. There is no valid risk assessment in patients with active cancer, so several cardiovascular and oncology-related factors are considered, including the CHADS-VASC score; HAS_BLED score; thromboembolic and bleeding risk of the malignancy; platelet count; and life expectancy (see Chapter 40, "Arrhythmias"). Anticoagulant selection should consider potential drug interactions with anticancer therapy. Rate control is typically preferred over rhythm control, particularly if the agent causing AF is continued. BB is commonly used due to the lack of drug-drug interactions. Cardiac ischemia is a rare cardiovascular toxicity from anticancer treatment.[59] Anti-microtubule agents (ie, taxanes and vinca alkaloids), anti-metabolites (ie, fluorouracil, capecitabine), platinum compounds (ie, cisplatin), and some VEGF inhibitors have been linked to ischemic events.[62] Baseline ECG and frequent vital sign monitoring are recommended for early detection.

SPECIAL CONSIDERATIONS

VTE Prevention and Management

VTE, which includes deep VTE (DVT) and pulmonary embolism (PE), is a common cause of cancer-associated morbidity and mortality. Potential pathophysiological causes for VTE in patients with cancer include known hypercoagulability (pro-coagulants expressed by cancer cells), vessel wall damage, and vessel stasis from direct tumor compression.[62] Several factors place patients at a higher risk of VTE, including the malignancy type and stage, systemic treatment used, surgery, RT, and use of indwelling catheters. Patient factors such as advanced age, comorbidities, previous VTE, hereditary thrombophilia, and immobilization and hospitalization also contribute to VTE risk. The risk of a patient with cancer developing a VTE is four- to sevenfold greater than the general population and is reported in up to 15% of patients each year.[63] Patients with cancer are also more likely to have higher rates of VTE recurrence and bleeding complications during VTE treatment.[63]

Prophylaxis

Routine prophylaxis is not recommended in all patients with cancer but is indicated in certain scenarios.[62,63] Patients with an active malignancy who are hospitalized should be offered thromboprophylaxis with unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) in the absence of bleeding or other contraindications. Patients who have major surgery for their cancer should receive thromboprophylaxis for at least 7 to 10 days. Patients who have a high-risk abdominal or pelvic cancer surgery should have VTE prophylaxis continued for up to 4 weeks postoperatively. Patients who are ambulatory receiving chemotherapy should be assessed for VTE risk utilizing the Khorana prediction model. Patients identified to have a high risk (Khorana score ≥ 2; see NCCN guidelines for score calculation) should be offered prophylaxis with apixaban, rivaroxaban, or LMWH for up to 6 months or longer if the risk persists. Patients diagnosed with multiple myeloma who are receiving treatment with immunomodulatory drugs may be indicated to receive VTE prophylaxis based upon their SAVED and IMPEDE VTE Score (see NCCN guidelines for score algorithms). Patients determined to be high risk should be offered enoxaparin, dalteparin, warfarin, or apixaban prophylaxis, while low risk patients may be offered no intervention or aspirin prophylaxis. Refer to the NCCN and ASCO guidelines for specific drug dosing recommendations.

Treatment

Once a patient is diagnosed with a VTE, treatment should be continued for at least 3 months or as long as the patient has active cancer or is receiving anticancer therapy.[62] For noncatheter associated clots, patients should be on anticoagulation indefinitely while the cancer is active, while they are receiving treatment, or if risk factors for recurrence persist. For a catheter-associated clot, patients should be on anticoagulation as long as the catheter is in place. The agent used for VTE treatment should be selected based upon a variety of factors: renal failure, hepatic disease, inpatient or outpatient status, FDA approval, cost, patient preference, ease of administration, monitoring, bleeding risk, and ability to reverse anticoagulation, if needed. Direct oral anticoagulants (DOACs), LMWHs, fondaparinux, and UFH are available options for initial treatment. Warfarin is not recommended as first-line therapy in patients with cancer, as LMWHs have been associated with a lower risk of recurrent VTE without an increased risk of major bleeding, but may be used for long-term anticoagulation in certain circumstances. DOACs are absorbed primarily in the stomach and proximal bowel (apixaban is partially absorbed in the colon) and may not be good options for patients who have had significant resections of these areas. DOACs should be used with caution in patients with genitourinary or GI tract lesions, pathology or instrumentation, since they have been associated with an increased risk of GI bleeding and possibly genitourinary tract bleeding. LMWH is preferred in these patients. Refer to the NCCN and ASCO guidelines for specific drug dosing recommendations.

Unique Considerations

Thrombocytopenia is a common complication of anticancer treatment and can place patients on anticoagulation at an increased risk of bleeding. Generally, anticoagulation is considered safe to use in patients with a platelet count of 50 × 10^9/L (50,000/mm^3) or more. The NCCN guidelines provide guidance for prophylactic and treatment dosing of anticoagulation in patients who are thrombocytopenic.[62] Some additional contraindications to anticoagulation include active bleeding, indwelling neuraxial catheters, neuraxial anesthesia/lumbar puncture, interventional spine, and pain procedures. The NCCN guidelines also offer further guidance on potential relative contraindications to anticoagulation and recommendations for holding anticoagulation around surgeries and procedures, including lumbar punctures. Patients with cancer are at risk for recurrent VTE and anticoagulation failure. Patients may require a change in dose, dosing, schedule, or agent. The NCCN guidelines also provide recommendations if this occurs.

Pain Management

Pain is one of the most common symptoms experienced by patients with cancer. It can be acute or chronic, and multiple possible etiologies such as the disease itself (eg, tumor invasion, organ obstruction), treatment (eg, chemotherapy, RT, and surgical incisions), or diagnostic procedures (eg, biopsy). Nociceptive and neuropathic are the two most predominant mechanisms of pain pathophysiology. To ensure proper management, a comprehensive pain assessment should be completed at the initial evaluation, at each subsequent contact, and at the start of a new therapy. The goals of pain management are to optimize patient treatment outcomes in five dimensions, also known as the 5A's of pain management outcomes: analgesia (optimize, analgesia), activities (optimize activities of daily living), adverse effects (minimize ADRs), aberrant drug-taking (avoid aberrant drug-taking), and affect (relationship between pain and mood). Treatment must be individualized considering clinical circumstances and patient wishes, with the goal of maximizing function and quality of life (see Chapter 79, "Pain Management" for more information).

It is important to determine if pain is related to an oncologic emergency, which is a life-threatening event directly or indirectly related to a patient's cancer or anticancer treatment. This includes pain due to bone fracture or impending fracture of weight-bearing bone, epidural or leptomeningeal metastases, pain associated with infection, or obstructed or perforated viscus. Oncologic emergency-related pain should be treated immediately while concurrently treating the underlying condition. Patients with pain not related to an oncologic emergency may be treated with a combination of pharmacologic analgesics; nonopioids (eg, NSAIDs or acetaminophen), opioids, and adjuvant analgesics (eg, antidepressants, anticonvulsants, topical agents, and corticosteroids) or nonpharmacologic integrative interventions (eg, physical, cognitive modalities, spiritual).

Adult cancer pain can be categorized by level of pain intensity (0-no pain, 10-worst pain; mild [1-3], moderate [4-7], and severe [8-10]) which can be used to help guide treatment decisions (Table 150-7). For patients with severe pain, pain crisis, or uncontrolled pain, hospital or inpatient hospice may be required for treatment due to the frequent need to reassess and adjust opioid dosing to achieve adequate pain control (Fig. 150-2). See Chapter 79, "Pain Management" and NCCN Adult Cancer Pain guidelines[64] for medication dosing, ADRs, drug interaction, and contraindication information. Patients may experience inadequate pain relief despite pharmacologic therapy or may not tolerate opioid titration due to ADRs. In these scenarios, interventional therapies may be approbation to eliminate or significantly reduce pain levels, and/or may allow a significant decrease in systemic analgesics. Some useful interventional therapies include nerve blocks, vertebral augmentation, regional infusion of analgesics, radiofrequency ablation, and others.[64]

TABLE 150-7

Cancer-Related Pain Treatment Recommendations

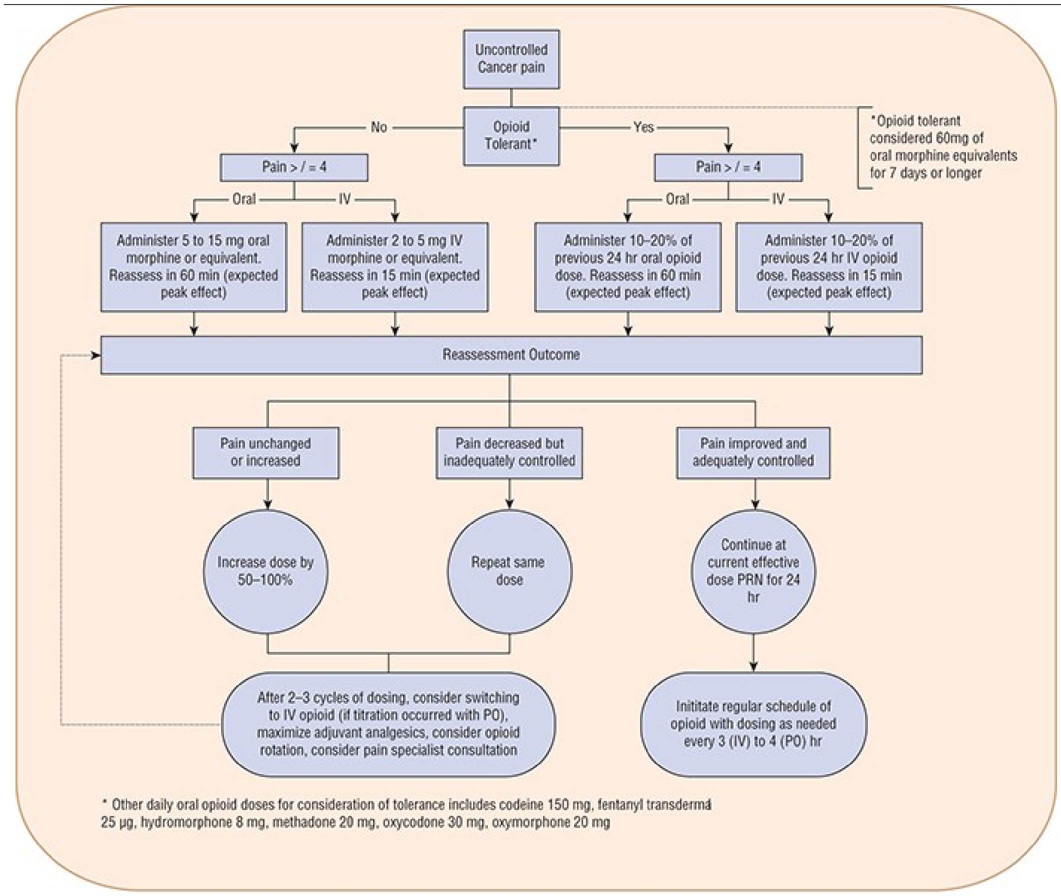
Pain Intensity (Numerical Rating Score)	Opioid-naïve	Opioid-tolerant
Mild (1-3)	• Nonopioid analgesics + adjuvant analgesics	• Nonopioid analgesics + adjuvant analgesics • Re-evaluate need for opioid analgesics and initiate gradual dose reductions if indicated
Moderate (4-6)	• Nonopioid analgesics + adjuvant analgesics + short-acting opioids as needed • Titrate every 3-4 hours • If ≥4 doses are needed/day, consider addition of long-acting opioid based on TDD	• Nonopioid analgesics + adjuvant analgesics + short-acting opioids as needed • Titrate short-acting opioids with goal of increasing TDD by 30%-50% until pain relief is achieved • If ≥4 doses are needed/day, consider addition or increase in dose of long-acting opioid based on TDD
Severe (7-10)	• Consider hospital or inpatient hospice admission • IV or oral short-acting opioids	

TDD, total daily dose.

Data from Reference 64.

FIGURE 150-2

Treatment algorithm for cancer pain crisis. Patients should first be assessed for opioid tolerance and then managed according to their pain score on the 0-10 numeric rating scale. Patients in pain crisis require frequent monitoring and reassessment of their pain score to determine if redosing of opioids are needed to achieve adequate pain control. (Data from NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines®). Adult Cancer Pain V.2.2021. National Comprehensive Cancer Network, Inc. Accessed July 29, 2021.



Uncontrolled Cancer pain
Opioid Tolerant*
No
Yes
*Opioid tolerant considered 60mg of oral morphine equivalents for 7 days or longer
Pain > / = 4
Pain > / = 4
Oral
IV
Oral
IV
Administer 5 to 15 mg oral morphine or equivalent. Reassess in 60 min (expected peak effect)
Administer 2 to 5 mg IV morphine or equivalent. Reassess in 15 min (expected peak effect)
Administer 10–20% of previous 24 hr oral opioid dose. Reassess in 60 min (expected peak effect)
Administer 10–20% of previous 24 hr IV opioid dose. Reassess in 15 min (expected peak effect)
Reassessment Outcome
Pain unchanged or increased
Pain decreased but inadequately controlled
Pain improved and adequately controlled
Increase dose by 50–100%
Repeat same dose
Continue at current effective dose PRN for 24 hr
After 2–3 cycles of dosing, consider switching to IV opioid (if titration occurred with PO), maximize adjuvant analgesics, consider opioid rotation, consider pain specialist consultation
Initiate regular schedule of opioid with dosing as needed every 3 (IV) to 4 (PO) hr
* Other daily oral opioid doses for consideration of tolerance includes codeine 150 mg, fentanyl transdermal 25 μg, hydromorphone 8 mg, methadone 20 mg, oxycodone 30 mg, oxymorphone 20 mg

Additional interventions may be needed for treatment in specific scenarios. Some specific cancer pain syndromes with unique treatment considerations include neuropathic pain, bone pain (not associated with an oncologic emergency), and pain from mucositis, pharyngitis and esophagitis (see "GI Toxicities: Diarrhea, Mucositis, and Nausea/Vomiting" section).

Neuropathic Pain

Cancer-related neuropathic pain can be caused by the cancer itself, or the acute or chronic effects of anticancer treatment.[64] Many chemotherapy agents including taxanes, platinums, vinca alkaloids, epothilones, eribulin, and bortezomib cause treatment-related neuropathy.[65] No agents are recommended for the prevention of chemotherapy-induced peripheral neuropathy (CIPN). Patients who develop intolerable neuropathy and/or functional impairment may require dose delays, reductions, substitutions of treatment, or discontinuation. Adjuvant analgesics commonly used to manage neuropathic pain include anticonvulsants (eg, pregabalin, gabapentin), antidepressants (eg, tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors), and topical treatments (eg, gel or patch lidocaine).[64] The ASCO CIPN guidelines support the use of duloxetine for patients with established painful CIPN[65]; however, the NCCN guidelines recommend antidepressants and anticonvulsants first-line.[64] Corticosteroids may also be used, particularly in the setting of radiculopathies from vertebral body compression fractures (see "Bone Health" section for more information). See Chapter 79, "Pain Management" and NCCN Adult Cancer Pain guidelines for medication dosing, ADRs, interaction and contraindication information.

Bone Pain (Not Oncologic Emergency)

Patients with bone metastases may also experience bone pain. Bone pain may be treated with NSAIDs, acetaminophen, or steroids in combination with opioids.[64] Topical diclofenac (gel or patch) may be considered to provide pain relief with minimal systemic effects. BMAs are used in patients with bone metastases for their role in reducing overall SREs, but they also provide modest pain relief and may be recommended in conjunction with other therapies (eg, systemic analgesics, surgery, RT).

LONG-TERM EFFECTS/SURVIVORSHIP

Anticancer agents pose a risk for a variety of long-term effects, including but not limited to organ damage, impact on reproductive organs, as well as immunologic and psychological effects. Advances in screening and early diagnosis of cancer as well as improvements in treatments have led to a higher number of survivors of cancer. Many institutions have multidisciplinary clinics for long-term survivors of cancer focused on monitoring and management of long-term complications of cancer and its treatments. Survivors should be assessed for long-term physical and psychosocial effects, including but not limited to organ dysfunction (eg, anthracycline-induced cardiotoxicity), pain or neuropathy, depression, cognitive dysfunction, as well as infertility and secondary malignancies.[66] Various consensus-based guidelines exist regarding long-term screening and follow-up for patients with cancer, often specific to initial disease and treatment regimens, which is beyond the scope of this chapter.[67]

Anticancer treatments may be affiliated with the risk of embryo-fetal toxicity and the risk of infertility due to gonadotoxicity. Before initiating regimens with the risk of embryo-fetal toxicity, pregnancy testing of patients of childbearing potential and counseling on adequate contraception to both male patients and female patients of childbearing potential is necessary. Notably, certain anticancer agents have specific contraception requirements and even Risk Evaluation and Mitigation Strategy, or REMS, programs, such as the immunomodulatory agents (eg, thalidomide, lenalidomide) due to known teratogenicity. In men, chemotherapy can produce oligospermia or azoospermia, as well as infertility; however, serum testosterone levels are rarely altered unless the patient is receiving hormonal therapy aimed at lowering testosterone (eg, androgen deprivation therapy). The recovery of spermatogenesis after completing therapy is unpredictable. Age, total dose, duration of therapy, combination chemotherapy, and the chemotherapy mechanisms are other important variables. In women, toxic effects on the ovaries result clinically in amenorrhea, vaginal epithelial atrophy, and menopausal symptoms. These effects are related to dose and age. Younger patients are more resistant to the effects on the ovaries. As with men, the recovery of fertility is unpredictable, but women younger than 25 years of age appear to have the best outcomes. The effects of the alkylating agents on fertility have been extensively studied finding profound and consistently detrimental effects on reproductive function. The risk of infertility with other anticancer agents is largely unknown. The risk of infertility should be discussed with all patients of childbearing potential (ie, informed consent and counseling) before they receive anticancer agents, and they should be informed about options for fertility preservation to allow for referral to fertility specialists if deemed desirable by the patient.[68,69]

Secondary cancers induced by anticancer agents or RT are serious long-term consequences.[70] For curable cancers, the relatively small risk for the occurrence of secondary malignancies is far outweighed by the benefits of survival. The risk of secondary malignancies is of particular concern in patients receiving adjuvant chemotherapy. The risk of secondary malignancies is highest after receiving certain cytotoxic chemotherapy agents, such as alkylating agents, anthracyclines, and epipodophyllotoxins. Most commonly the secondary malignancy is a treatment-related myelodysplastic syndrome (MDS) or acute myeloid leukemia (AML), often approximately 5 to 7 years after initial exposure and presenting with a deletion in chromosome 5 or 7. Overall, the prognosis for secondary AML is worse than *de novo* disease. Further, these patients are at risk for secondary solid tumors, such as lung, skin, or breast cancers, typically 10 to 20 years after initial alkylating agent exposure.[70] Cytotoxic chemotherapy is not the only anti-cancer treatment with the risk of subsequent cancer diagnosis. Exposure to radiation can increase the risk of secondary cancers. Additionally, exposure to certain oral anticancer agents, such as poly(ADP-ribose) polymerase, or PARP, inhibitors, which can increase the risk of myelodysplastic syndrome and AML[71] and BRAF inhibitors which can increase the risk of squamous cell carcinoma.[72]

CONCLUSION

Patients with cancer are at risk for a variety of disease- and treatment-induced complications. Clinicians should consider the type of cancer as well as patient- and treatment-specific risk factors for each complication to provide adequate monitoring, prophylaxis, and evidence-based interventions for management.

ABBREVIATIONS

5-HT3-RA	5-hydroxytryptamine/serotonin receptor antagonist

ACEIs	angiotensin converting enzyme inhibitors
ADR	adverse drug reaction
AF	atrial fibrillation
ALK	anaplastic lymphoma kinase
ANC	absolute neutrophil count
ARBs	angiotensin receptor blockers
ASCO	American Society of Clinical Oncology
BB	beta blocker
BP	blood pressure
BMA	bone-modifying agent
BRAF	v-raf murine sarcoma viral oncogene homolog B1
CAR-T	chimeric antigen receptor T cell
CIA	chemotherapy-induced alopecia
CINV	chemotherapy-induced nausea and vomiting
CIPN	chemotherapy-induced peripheral neuropathy
CNS	central nervous system
CRS	cytokine release syndrome
CSF	colony-stimulating factor
CT	computed tomography
CTCAE	common toxicity criteria for adverse events
CTLA4	cytotoxic T-lymphocyte-associated protein 4
DOAC	direct oral anticoagulant
ECG	electrocardiogram
ECHO	echocardiogram
EEG	electroencephalogram
EGFR	epidermal growth factor receptor

ESA	erythropoiesis-stimulating agent
FDA	Food and Drug Administration
FN	febrile neutropenia
G6PD	glucose-6-phosphate dehydrogenase
GI	gastrointestinal
GnRH	gonadotropin-releasing hormone
HSCT	hematopoietic stem cell transplantation
HEC	highly emetogenic chemotherapy
HER2	human epidermal growth factor receptor 2
HF	heart failure
HFS	hand-foot syndrome
HFSR	hand-foot skin reaction
HTN	hypertension
HLA	human leukocyte antigen
ICANS	immune effector cell-associated neurotoxicity syndrome
ICI	immune checkpoint inhibitor
IrAE	immune-related adverse event
IV	intravenous
LEC	low emetogenic chemotherapy
LMWH	low-molecular-weight heparin
LVD	left ventricular dysfunction
LVEF	left ventricular ejection fraction
MEC	moderately emetogenic chemotherapy
MEK	mitogen-activated protein kinase
mTOR	mammalian target of rapamycin
MUGA	multigated acquisition

NCCN	National Comprehensive Cancer Network
NCI	National Cancer Institute
NSAIDs	nonsteroidal anti-inflammatory drugs
N/V	nausea/vomiting
PD-1	programmed cell death protein 1
PD-L1	programmed death-ligand 1
PI3K	phosphoinositide-3 kinase
PO	oral
PRN	as needed
RT	radiation therapy
SCr	serum creatinine
SQ	subcutaneously
SRE	skeletal-related event
TLS	tumor lysis syndrome
TNF	tumor necrosis factor
TKI	tyrosine kinase inhibitor
UFH	unfractionated heparin
ULN	upper limit of normal
VEGF	vascular endothelial growth factor
VTE	venous thromboembolism
WBC	white blood cell

SELF-ASSESSMENT QUESTIONS

1. According to NCCN guidelines, which of the following is the most appropriate indication for a granulocyte CSF product, such as filgrastim?
    A. To enhance the recovery of red blood cells after radiation-containing therapy
    B. To enhance the recovery of neutrophils after chemotherapy which has ≥20% risk of febrile neutropenia
    C. To enhance the recovery of platelets after chemotherapy which has >30% risk of thrombocytopenia
    D. To enhance the recovery of platelets and red blood cells after allogeneic hematopoietic cell transplantation
2. Which of the following medications can be used in the prevention of mucositis?
    A. Atropine
    B. Darbepoetin
    C. Filgrastim
    D. Palifermin
3. Which of the following is a risk factor for chemotherapy-induced nausea and vomiting (CINV)?
    A. Age <50 years
    B. Concomitant alcoholism
    C. Concomitant depression or anxiety
    D. Male gender
4. Which of the following is the most appropriate strategy to prevent acute CINV for a patient who is receiving intravenous HEC?
    A. NK1-RA, 5HT3-RA, corticosteroid, and olanzapine
    B. Olanzapine and corticosteroid
    C. 5HT3-RA and corticosteroid
    D. 5HT3-RA alone
5. A warm compress should be applied as part of the initial management following extravasation of which of the following chemotherapy agents?
    A. Daunorubicin
    B. Cisplatin
    C. Paclitaxel
    D. Vinca alkaloid
6. Which of the following is the most appropriate treatment of hyperuricemia for a patient diagnosed with clinical tumor lysis syndrome?
    A. Calcium gluconate plus sevelamer
    B. Hydration plus rasburicase
    C. Insulin plus dextrose
    D. Sodium bicarbonate plus inhaled albuterol

7. Which of the following statements regarding irAEs is true?
    - A. Patients commonly require dose reductions to manage irAEs.
    - B. irAEs occur due to lack of an immune response.
    - C. The most common irAE is myelosuppression.
    - D. Corticosteroids or other immunosuppressive agents are used to manage irAEs.
8. Which of the following statements is accurate regarding AEs post-CAR-T?
    - A. Temperature, oxygen saturation, and blood pressure are necessary monitoring parameters for CRS
    - B. CRS is prevented with administration of prophylactic corticosteroids
    - C. Neurotoxicity has an onset typically within the first several days of CAR-T infusion
    - D. Neurotoxicity is managed with the anti-IL6 agent tocilizumab monotherapy
9. How should a patient with a mild (grade 1) acneiform rash be managed?
    - A. Topical corticosteroids
    - B. Tetracycline antibiotics
    - C. Both topical corticosteroids and tetracycline antibiotics
    - D. Benzoyl peroxide
10. Which cancer treatment is associated with the toxicity of hyperglycemia?
    - A. BCR-ABL TKIs
    - B. c-KIT TKIs
    - C. mTOR inhibitors
    - D. Radiation therapy
11. Which of the following patients would be considered high risk for development of osteoporosis and may need bone-modifying therapy?
    - A. 21-year-old female on GnRH agonists to cause ovarian suppression while on chemotherapy
    - B. 42-year-old female with metastatic breast cancer on chemotherapy
    - C. 52-year-old male with AML receiving 3 days of dexamethasone for CINV prophylaxis
    - D. 63 year-old-male with prostate cancer who just completed radiation therapy
12. Which of the following drug classes is associated with hypertension?
    - A. Anthracyclines
    - B. ICIs
    - C. Proteasome inhibitors

D. VEGF inhibitors

13. Which of the following statements regarding anticoagulation in cancer patients is correct?

    A. Anticoagulation is generally considered safe as long as the patient has a platelet count of at least 50,000/mm^3 (50 × 10^9/L).

    B. Ambulatory patients with a Khorana score of 1 or greater are considered high risk for VTE and should be offered prophylaxis.

    C. DOACs are preferred in patients with gastrointestinal cancers.

    D. Warfarin is the preferred first-line agent for VTE treatment.

14. Which of the following agents would be appropriate to recommend and supported by the ASCO guidelines to manage chemotherapy-induced peripheral neuropathy?

    A. Duloxetine

    B. Methadone

    C. Oxycodone

    D. Sertraline

15. When counseling a patient about long-term complications from cancer treatment, which of the following statements is most accurate regarding secondary malignancies to tell the patient?

    A. Agents with the highest risk of leading to diagnosis of secondary cancers are the ICIs

    B. Most commonly diagnosed secondary malignancies are myelodysplastic syndrome and AML

    C. Patients diagnosed with a secondary leukemia have improved prognosis compared to those with a de novo diagnosis

    D. Secondary malignancies with solid tumors are most likely to be diagnosed in the first 5 to 7 years after initial cancer treatment

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** GCSF is utilized for prophylaxis of chemotherapy-induced neutropenia for regimens with ≥20% risk of febrile neutropenia as per NCCN Hematopoietic Growth Factors Guideline. See section "Hematologic Toxicities: Anemia, Neutropenia, and Thrombocytopenia."

2. **D.** Palifermin is indicated to prevent chemotherapy-induced mucositis in specific patient populations. See section "GI Toxicities: Diarrhea, Mucositis, and Nausea/Vomiting."

3. **C.** Concomitant depression/anxiety, age >50 years, and female gender are risk factors. See section "GI Toxicities: Diarrhea, Mucositis, and Nausea/Vomiting."

4. **A.** Guidelines recommend quadruplet therapy for acute prophylaxis for IV HEC regimens with an NK1-RA, 5HT3-RA, dexamethasone and olanzapine. While triplet prophylaxis is an option for HEC, the appropriate triplet regimen would be an NK1-RA or olanzapine plus dexamethasone and a 5HT3-RA. See section "GI Toxicities: Diarrhea, Mucositis, and Nausea/Vomiting" and Table 150-1.

5. **D.** Only vinca alkaloid agents are managed with warm compress after extravasation. See section "ONCOLOGIC EMERGENCIES: TLS AND EXTRAVASATION, PATIENT CARE PROCESS" and Table 150-3.

6. **B.** Hydration and rasburicase are indicated to manage hyperuricemia. See section "Oncologic Emergencies: TLS and Extravasation" and Table 150-2.

7. **D.** irAEs typically require treatment with corticosteroids or other immunosuppressive agents. Therapy is held or discontinued, not dose-reduced.

irAEs are a result of immune system activation and do not include myelosuppression. See section “Immune-Related Adverse Events”.

8. **A.** CRS monitoring includes fever, oxygen saturation, and blood pressure. Corticosteroids are not indicated to prevent CRS or ICANS. ICANS typically has an onset after at least a week of CAR-T infusion and is managed primarily with corticosteroid. CRS, not ICANs, can be managed with tocilizumab. See section “Cellular Immunotherapy ADRs: CRS and Neurotoxicity.”
9. **C.** Both topical and oral agents should be used to manage acneiform rash. Traditional acne medications like benzoyl peroxide should be avoided. See section “Dermatologic Toxicities” and Table 150-4.
10. **C.** mTOR inhibitors are linked with the development of hyperglycemia. The other agents are not. See section “Endocrine Toxicities.”
11. **A.** Premenopausal women receiving GnRH therapies causing ovarian suppression are at risk for rapid bone loss and should be considered to bone-modifying treatment. See section “Bone Health.”
12. **D.** VEGF inhibitors are associated with the cardiovascular toxicity of hypertension. The other answer choices are associated with other cardiac toxicities. See section “Cardiovascular Toxicities.”
13. **A.** Thrombocytopenia is a common complication of cancer treatment and the use of anticoagulation must be balanced with the increased risk for bleeding. However, anticoagulation is generally considered safe to use as long as the patient has a platelet count of at least 50,000/mm^3 (50 × 10^9/L). See section “Special Considerations – VTE Prevention and Management”.
14. **A.** Duloxetine is the only agent recommended by the ASCO guidelines for the management of CIPN. While opioids may have benefit in cancer pain management, they are not beneficial in CIPN and not recommended by the ASCO guidelines. See section “Special Considerations – Pain Management.”
15. **B.** ICIs are not affiliated with secondary malignancies. Most common secondary malignancies are myelodysplastic syndrome/AML which are most likely in first 5 to 7 years after initial cancer treatment and have a poorer prognosis than de novo disease. Secondary solid tumor diagnosis typically occurs 10 to 20 years after initial treatment. See section “Long-Term Effects/Survivorship.”

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 151: Breast Cancer

Bonnie Lin Boster; Neelam K. Patel; Jaime Kaushik

KEY CONCEPTS

KEY CONCEPTS

① Breast cancer is usually diagnosed in the early stages when it is highly curable.

② Although controversial, regular screening mammography in women younger than 50 years of age is beneficial, and many studies demonstrate that annual or biennial screening mammography in women aged 50 to 74 years reduces the breast cancer mortality rate.

③ Local therapy of early-stage breast cancer consists of modified radical mastectomy or lumpectomy plus external-beam radiation therapy. The surgical approach to the ipsilateral axilla may consist of a lymph node mapping procedure with sentinel lymph node biopsy or a full-level I/II axillary lymph node dissection. Breast conserving therapy (BCT) includes lumpectomy, surgical evaluation of the lymph node basin, and radiation.

④ The goal of adjuvant and neoadjuvant chemotherapy is cure while the goal of chemotherapy in the metastatic setting is palliation.

⑤ Adjuvant endocrine therapy reduces the rates of relapse and death in patients with hormone receptor–positive early breast cancer. Adjuvant chemotherapy reduces the rates of relapse and death in all patients with early-stage breast cancer.

⑥ The choice of the most appropriate chemotherapy, endocrine therapy, and human epidermal growth factor receptor (EGFR)-2 (*HER2)*–targeted therapy regimen is complex and rapidly changes as results from ongoing randomized clinical trials are reported.

⑦ Neoadjuvant chemotherapy and biotherapy are appropriate for selected patients with early breast cancer and most patients with locally advanced and inflammatory breast cancer (IBC) followed by local therapy and further adjuvant systemic therapy as indicated.

⑧ About 55% of women with metastatic breast cancer (MBC) will respond to chemotherapy regimens; anthracycline- and taxane-containing regimens are the most active.

⑨ Initial therapy of MBC in most women with hormone receptor–positive tumors should include endocrine therapy.

⑩ *HER2*-targeted therapies and other biologic or targeted agents (eg, everolimus, cyclin-dependent kinase [CDK] inhibitors) in combination with chemotherapy or endocrine therapy are options for patients with MBC.

BEYOND THE BOOK

BEYOND THE BOOK

Activity #1

Learners are encouraged to review “Breast Cancer: An Opportunity Lost Level II” in the *Pharmacotherapy Casebook: A Patient-Focused Approach* to practice applying their knowledge to develop a patient-centered care plan for a patient with breast cancer.

INTRODUCTION

In this chapter, the term “women” and “men” are used to reflect gender identified in previous research studies and other literature on breast cancer and to recognize the biological sex of individuals at birth. In doing so, we recognize that not all patients with breast cancer identify as females or males at the time of diagnosis and treatment of breast cancer. Breast cancer is the most common cancer and is second only to lung cancer as a cause of cancer death in American women. About 284,200 new cases of breast cancer were diagnosed and 44,130 people died of breast cancer in 2021.[1] In addition to invasive breast cancers, 49,290 cases of noninvasive, ductal carcinoma in situ (DCIS), cancer were diagnosed among women in the United States in 2021.[1]

Breast cancer incidence rates increased in the 1980s and decreased starting in 2000. The decreased incidence is thought to be related to decreased use of menopausal hormone therapy, also known as hormone replacement therapy (HRT), in postmenopausal individuals.[2] The incidence of DCIS also increased during the 1980s, due to the increased use of screening mammography.[2] Since 2004, breast cancer has slowly increased by about 0.3% per year, and during 2012 to 2016, DCIS has decreased by about 2.1% per year.[2] The increase in breast cancer incidence has been attributed to increases in body mass index (BMI) and declines in the average number of births per individual.[2]

Breast cancer incidence rates vary considerably across racial and ethnic groups in the United States. For example, the average annual age-adjusted incidence rate from 2012 to 2016 was 130.8 cases per 100,000 among non-Hispanic White women, 126.7 cases among non-Hispanic Black women, 94.7 cases in American Indian/Alaska Native women, 93.7 cases in Hispanic women, and 93.2 cases among Asian/Pacific Islander women.[2] The higher incidence rates in White women than in other racial and ethnic groups may be related to differences in reproductive and lifestyle factors and access to and use of screening.

① For all racial and ethnic groups, most breast cancers are diagnosed at an early stage when tumors are small and localized. Unfortunately, breast cancer mortality is higher among Black women compared to White women despite the lower incidence. The cause of this disparity between White and Black women is widely debated and multifactorial, and proposed explanations include differences in stage at diagnosis, tumor characteristics, obesity, comorbidities, access to care, early detection, and treatment.[2] Overall breast cancer mortality rates in the United States have declined since 1990; this decline has been attributed to improvements in early detection and treatment.[2]

The median age at diagnosis for breast cancer is 62 years.[2] Although lung cancer is the leading cause of cancer deaths for women regardless of age, breast cancer is the leading cause of cancer deaths for women between the age of 20 and 59 years.[1]

EPIDEMIOLOGY AND ETIOLOGY

The two variables most strongly associated with the occurrence of breast cancer are biological sex and age. Although one commonly thinks of breast cancer as a disease confined to women, about 2,650 cases of breast cancer are estimated to be diagnosed in men in the United States in 2021.[1] Men are more likely to have more advanced disease at the time of diagnosis. Men also have lower unadjusted rates of overall survival than women with breast cancer. This difference is not only due to advanced disease at diagnosis but also older age at diagnosis as well as shorter life expectancy in general.[3] Treatment of breast cancer is similar regardless of sex or gender.

The incidence of breast cancer increases with advancing age. A frequently quoted breast cancer statistic is that one in eight women will develop breast cancer during her lifetime. It should be emphasized that this is a cumulative lifetime risk of developing the disease from birth to death. The one-in-eight women figure is often misinterpreted by women who assume that it translates into one in eight women being diagnosed with breast cancer each year. A more useful method of presenting the risk data is based on age intervals. For example, the 10-year probability of breast cancer diagnosis of a 20-year-old individual is 1 in 1479, but this risk changes to 1 in 28 for a 60-year-old individual.

A number of calculators are available to estimate a woman's risk of developing breast cancer. The National Cancer Institute (NCI) has an online version of the Breast Cancer Risk Assessment Tool (https://bcrisktool.cancer.gov/calculator.html). This tool is based on a statistical model known as the Gail model, derived from a mammography screening project conducted in the 1970s. It was designed for health professionals to project an individualized risk for invasive breast cancer over a 5-year period and over their lifetime. This model has been shown to provide accurate estimates in several racial and ethnic groups, but it has not been validated for those with genetic risk factors, a previous history of in situ or invasive breast cancer, or for certain subgroups. Other risk assessment models also exist, each taking into account different risk factors.

Endocrine Factors

Many endocrine factors have been associated with the risk of breast cancer. Many of these relate to the total duration of menstrual life. Early menarche, generally defined as menstruation beginning before age of 11 years, increases the cumulative lifetime risk of breast cancer development. Similarly, a late age of natural menopause (age 55 years or later) increases the risk of breast cancer development.[2] Conversely, bilateral oophorectomy before the age of 45 years reduces the risk of developing breast cancer.[4] Nulliparity and a late age at first birth (greater than or equal to 30 years) are reported to increase the lifetime risk of developing breast cancer.[2] Investigators postulate that international differences in age of menarche, age at menopause, and childbearing may account for a substantial part of the international differences in the incidence of breast cancer.

Many studies have evaluated the relationship between exogenous hormones and the development of breast cancer. The Women's Health Initiative (WHI) is a series of clinical trials designed to investigate the risks and benefits of treatment strategies that could affect women's health issues, such as breast cancer. The estrogen plus progestin trial reported an increased risk of breast cancer in women taking combined estrogen and progestin. In the estrogen alone trial, which included postmenopausal women with prior hysterectomy, the incidence of breast cancer was lower in those who received estrogen alone compared with those who received placebo.[2] Unresolved issues remain as to whether lower doses or short-term use of estrogen or estrogen–progestin for menopausal symptoms can be safe and effective. A longer duration of HRT and concurrent use of progestins contribute to breast cancer risk. In addition, the impact of HRT use on breast cancer risk also varies according to BMI and breast density.[2] The use of postmenopausal HRT in individuals with a history of breast cancer is generally contraindicated. Individuals who are considering HRT should carefully consider the risks versus benefits (see Chapter 102, "Hormone Therapy in Women for a detailed discussion of HRT").

Epidemiologic studies of oral contraceptives do not show a consistent relationship between the use and breast cancer risk. Results are conflicting, and assessment of the studies should consider the particular oral contraceptive products involved, daily and cumulative doses of the hormones administered, and latency period for development of breast cancer. It is also important to note that oral contraceptives are known to reduce the risk of ovarian and endometrial cancers.[5] Benefits and risk associated with oral contraceptives should be considered and discussed with each patient.

Genetic Factors

Both personal and family histories influence a woman's risk of developing breast cancer. A personal history of breast cancer is associated with an increased risk of developing contralateral breast cancer. Cancers of the uterus and ovary are also associated with an increased risk of developing breast cancer. Several cancer family syndromes include breast cancer in association with other types of cancers.

About 10% of all breast cancers in the US population can be attributed to family history. Empirical estimates of the risks associated with particular patterns of family history of breast cancer indicate the following[2,4]:

1. Having any first-degree relative with breast cancer increases a woman's risk of breast cancer about 50%. Risk increases with increasing numbers of affected first-degree relatives.
2. The risk is affected by both the woman's age and the age of the relative when diagnosed. A higher risk is seen when a woman and her relative at diagnosis are younger than 50 years.
3. The risk associated with having any second-degree relative with breast cancer is complex and depends on other family history patterns. The risk is

generally lower than that of first-degree relatives.

4. Affected family members on both the maternal and the paternal sides are important to consider in the evaluation of risk.

Although individuals with a family history of breast cancer are at increased risk for the disease, the diagnosis of breast cancer is still uncommon in young individuals even with a positive family history.

Germline mutations in either *BRCA1* or *BRCA2* are associated with an increased risk for breast and ovarian cancer. These genes function as tumor suppressor genes, maintaining genomic integrity and DNA repair. Compared with an average individual's 10% lifetime risk of developing breast cancer, the probability of developing breast cancer by the age of 80 years in individuals with a *BRCA1* or *BRCA2* mutation is estimated to be 70%.[2]

The probability of being a *BRCA* gene mutation carrier is related to ethnicity and family history. Ashkenazi (Eastern European) Jewish descendants have an unusually high (2.5%) carrier rate of germline mutations in *BRCA1* and *BRCA2* compared with the rest of the US population.[2] Conversely, clinically significant *BRCA* mutations occur at a frequency of about one in 400 persons in the general, non-Jewish US population.[2] Testing for *BRCA1* and *BRCA2* mutations is now widely available, but it is generally recommended only when there is personal or family history suggestive of hereditary cancer, when the test results can be adequately interpreted, and when results will assist with diagnosis and management. The decision to test an individual for a genetic mutation related to breast cancer risk is complex, and several organizations have published recommendations on genetic susceptibility testing for individuals who meet the criteria for increased risk.[6]

Although most genetic causes of breast cancer are attributed to *BRCA1* and *BRCA2,* other genes that have been associated with hereditary breast cancer include *TP53*, *CHEK2*, *PALB2*, *PTEN*, *ATM*, *STK11*, *CDH1*, and others.[6]

Environmental and Lifestyle Factors

Breast cancer incidence rates vary considerably among countries, which suggests that environmental and lifestyle factors play an important role. See Table 151-1 for details.

TABLE 151-1

Environmental and Lifestyle Factors

Factor	Comments
Elevated Risk	
Alcohol consumption	Some evidence that consumption before first pregnancy may affect risk; women who have 2-3 alcoholic drinks per day have a 20% higher risk compared to non-drinkers
Tobacco	Slight increase, notably in long-term, heavy smokers who started smoking before first pregnancy
Radiation exposure	Exposure particularly if before 10-30 years of age, eg, Hodgkin lymphoma
Reduced Risk	
Diet: Fruit and vegetable intake	Limited but increased evidence
Physical activity	Has protective effect independent of BMI
No Association	
Diet: Fat intake	No association based on recent meta-analysis
Mixed Results	
Diet: Soy	Reduced risk in Asian women but not the case with Western populations
Excess body weight/weight gain	Reduced risk in premenopausal women but elevated risk in postmenopausal women

Data from Reference 2.

Several endocrine, genetic, environmental, and lifestyle factors are associated with the development of breast cancer to varying degrees. Some factors are modifiable, but others are not. The impact of individual risk factors may vary depending on other confounding variables such as age, family history, estrogen use, and menopausal status. Further studies are needed to confirm the importance of factors that are associated with the risk of developing breast cancer.

PREVENTION AND EARLY DETECTION

Current efforts at breast cancer prevention are directed toward the identification and removal of risk factors often referred to as risk-reducing strategies. Prophylactic bilateral mastectomies or bilateral salpingo-oophorectomy are considered for individuals who are at high risk for the development of breast or ovarian cancer, particularly if the breast tissue is difficult to evaluate by both physical examination and mammography and if the individual have persistent disabling fears that they will be diagnosed with cancer. Guidelines for the incorporation of surgical risk-reducing strategies are largely based on genetics and other known risk factors for the development of breast (or ovarian) cancer.

Numerous agents are available for pharmacologic risk reduction, including the selective estrogen receptor modulators (SERMs), tamoxifen and raloxifene, and aromatase inhibitors (AIs), anastrozole and exemestane. Tamoxifen (20 mg/day × 5 years) reduces the risk of invasive and noninvasive estrogen receptor (ER)-positive breast cancers in individuals with a high risk for breast cancer by about 50%.[4] Tamoxifen has been shown to be a relatively safe drug with an acceptable toxicity profile when used to treat pre- or postmenopausal patients with breast cancer. Toxicities associated with tamoxifen are described in the "Endocrine Therapy" section under Curative Breast Cancer. Similarly, raloxifene (60 mg/day × 5 years), reduces the rates of noninvasive and invasive breast cancers in high-risk, postmenopausal individuals, but not to the same degree as tamoxifen does. Both agents increased thromboembolic events while only tamoxifen increases rates of endometrial cancer.[4] Although the benefits of raloxifene have decreased compared to tamoxifen, it may still be the treatment of choice when considering toxicities.[4]

A similar reduction in the risk of contralateral primary breast cancers was demonstrated with the AIs, exemestane and anastrozole. Both exemestane (25 mg/day × 3 years) and anastrozole (1 mg/day × 5 years) reduce rates of invasive breast cancers in high-risk, postmenopausal individuals and have tolerable adverse drug reactions. AIs have not been compared to SERMs and both classes of agents are appropriate options.[4] Although neither exemestane nor anastrozole is Food and Drug Administration (FDA) approved for breast cancer risk reduction, the American Society of Clinical Oncology, or ASCO, and National Comprehensive Cancer Network (NCCN) guidelines include AIs as acceptable options for risk reduction in postmenopausal women.[4,7] Any decision to use tamoxifen, raloxifene, or the AIs for risk reduction should be made after a thorough discussion of the woman's risk of breast cancer, the potential benefits, and the potential serious adverse drug reactions.

The rationale for early detection of breast cancer is based on the relationship between the stage of breast cancer at diagnosis and the probability of cure. If all breast cancer cases could be detected at an early stage of the disease (ie, small primary tumor and negative lymph nodes), then more patients theoretically could be cured of their disease. Screening guidelines for early detection of breast cancer in women at average risk have been developed by several organizations, including but not limited to the American Cancer Society (ACS), the United States Preventive Services Task Force (USPSTF), and the NCCN (see Table 151-2).[8–10] The ACS guidelines are most commonly cited. However, it is important to note that the expert panels developing these guidelines often differ in their approach and analysis of the available data, as is evident in the different recommendations in the guidelines.

TABLE 151-2

Breast Cancer Screening Guidelines

Risk Category	ACS	USPSTF	NCCN
Average Risk			
BSE	Not recommended but encourages breast awareness	Not recommended	Age ≥25 years: breast awareness
CBE	Evidence does not support	Insufficient evidence	Age ≥25-39 years: every 1-3 years
			Age ≥40 years: annually
Mammography	Age 40-44 years: opportunity annually	Age 40-50 years: individualized decision	Age ≥40 years: annually; consider tomosynthesis
	Age 45-54 years: annually	Age 50-74 years: biennial	
	Age ≥55 years: biennially or opportunity annually (as long as in good health and at least 10-year life expectancy)	Age >75 years: insufficient evidence	
High Risk[a,b]			
BSE	NA	NA	All ages: breast awareness
CBE	NA	NA	All ages: every 6-12 months
Mammography	Age ≥30 years: annually with MRI	NA	Prior RT or strong family history or genetic predisposition, age ≥25 years: annually (+ CBE); consider tomosynthesis
			All other categories: annually (+ CBE); consider tomosynthesis
Breast MRI	Age ≥30 years: annually with mammogram	NA	Annually with mammogram + CBE for (a) prior RT, age ≥25 years; (b) lifetime risk >20%; (c) consider MRI if history of LCIS or ADH/ALH and lifetime risk >20%

ACS, American Cancer Society; ADH, atypical ductal hyperplasia; ALH, atypical lobular hyperplasia; BSE, breast self-examination; CBE, clinical breast examination by a healthcare professional; LCIS, lobular carcinoma in situ; MRI, magnetic resonance imaging; NA, not addressed; NCCN, National Comprehensive Cancer Network; RT, thoracic radiation therapy; USPSTF, United States Preventive Services Task Force.

[a] High risk is defined by the ACS as women with (1) a known *BRCA1/2* gene mutation; (2) untested woman with first-degree relative with a known *BRCA1/2* gene mutation; (3) lifetime risk of breast cancer of 20%-25% or greater using a risk-assessment tool based largely on family history; (4) radiation therapy to the chest between the ages of 10 and 30 years; (5) LiFraumeni syndrome, Cowden syndrome, or Bannayan-Riley-Ruvalcaba syndrome or have first-degree relatives with one of these syndromes.

[b] High risk is defined by the NCCN as women with (1) prior thoracic radiation therapy before age 30 years, (2) 5-year risk of ≥1.7% of invasive breast cancer in women

≥35 years old, (3) lifetime risk of >20% as defined by models that are largely based on family history, (4) strong family history or genetic predisposition, (5) LCIS or ADH/ALH and lifetime risk of >20%, (6) prior history of breast cancer.

Data from References 2, and 8–10.

② The most controversial screening recommendation for breast cancer is annual mammography. Although screening mammography clearly decreases mortality from breast cancer, the controversies surround the balance of benefits and harms associated with a less than perfect screening test in individuals of different ages at average risk of developing breast cancer. The largest benefit for the number needed to invite for screening to prevent one breast cancer death was seen for women aged 60 to 69 years old.[11] Incorporation of this information into national guidelines differs with each organization (Table 151-2).

Other radiologic methods of breast imaging are also being investigated (eg, digital mammography [two-dimensional, 2D], digital breast tomosynthesis [also known as tomosynthesis or three-dimensional mammography], ultrasonography, and magnetic resonance imaging [MRI]). Recommendations regarding these other radiologic methods vary among the national guidelines and definitions of “high risk” also vary among the guidelines (Table 151-2). It should also be noted that any screening procedure has risks and they should be discussed with patients so they are able to make an informed decision regarding these procedures. The risks involved with screening mammograms include false-negative results, false-positive results, overdiagnosis (true positives that will not become clinically significant), and radiation risk. The rate of false-negative results with the current technology is about 20%.[12] Although the specificity of mammography is quite high (90%), most abnormal examinations are false-positive results, leading to additional biopsies and psychological distress.[11] The term “overdiagnosis” refers primarily to the increased detection of DCIS from screening mammography (see “Noninvasive Carcinoma” section for a detailed discussion of DCIS).

CLINICAL PRESENTATION

CLINICAL PRESENTATION

General

- The patient may not have any symptoms because breast cancer may be detected in asymptomatic patients through routine screening mammography.

Local Signs and Symptoms

- A painless, palpable lump is most common.
- Less common: pain; nipple discharge, retraction, or dimpling; skin edema, redness, or warmth.
- Palpable local–regional lymph nodes may also be present.

Signs and Symptoms of Systemic Metastases

- Varies depending on the site of metastases, but may include bone pain, difficulty breathing, abdominal pain or enlargement, jaundice, or mental status changes.

Laboratory Tests

- Tumor markers such as cancer antigen 15-3, or CA 15-3, or carcinoembryonic antigen, or CEA, may be elevated in patients with metastatic disease.
- Alkaline phosphatase or liver function test results may be elevated in patients with metastatic disease.

Other Diagnostic Tests

- Mammography (with or without ultrasonography, breast MRI, or both).
- Biopsy for pathology review and determination of tumor ER, progesterone receptor (PR), and *HER2* status.
- Systemic staging tests may include chest radiography, chest computed tomography (CT), bone scan, abdominal CT or ultrasonography, or MRI.

A painless lump is the initial sign of breast cancer in most women. The typical malignant mass is solitary, unilateral, solid, hard, irregular, and nonmobile. In small numbers of cases, stabbing or aching pain is the first symptom. Less commonly, nipple discharge, retraction, or dimpling may herald the onset of the disease. In more advanced cases, prominent skin edema, redness, warmth, and induration of the underlying tissue may be observed.

The breast is a complex organ composed of skin, subcutaneous tissue, fatty tissue, and branching ductal and glandular structures (Fig. 151-1). Various diseases that affect these structures can produce a palpable mass. In addition, the physiologic changes associated with the menstrual cycle can cause normal breast changes. Common causes of breast masses in young individuals are fibroadenoma, fibrocystic disease, carcinoma, and fat necrosis.

FIGURE 151-1

Breast anatomy. An illustration shows the cross-section of the breast. The breast lies posterior to the ribs and muscles and consists of fatty tissues and connective tissues. The ducts in the breast lead to the opening in the nipple. A normal duct or lobule is hollow, while the one with cancer is blocked.

Breast cancer that is confined to a localized breast lesion is often referred to as *early*, *primary*, *localized*, or *curable*. Breast cancer that has spread to local–regional lymph nodes is still considered early stage (see Fig. 151-2). Unfortunately, breast cancer cells often spread by contiguity, through lymph channels, and through the blood to distant sites. When breast cancer cells can be detected clinically or radiologically in sites distant from the breast, the disease is referred to as *advanced* or *metastatic* breast cancer (MBC). Tissues most commonly involved with distant metastases are lymph nodes (other than local–regional lymph nodes), skin, bone, liver, lungs, and brain. Symptoms of bone pain, difficulty breathing, abdominal enlargement, jaundice, and mental status changes may herald the clinical presentation of MBC. A small percentage of women have signs and symptoms of distant metastases when they first seek treatment. In virtually all of them, a neglected breast mass has been present for several months to years. In addition, 20% to 30% of all patients who initially present with early breast cancer will eventually develop signs and symptoms of MBC.[13]

FIGURE 151-2

Lymph node anatomy. An illustration shows that the position of nodes as follows: supraclavicular, mediastinal, internal mammary, interpectoral or Rotter’s, proximal or lower axillary, central or middle axillary, distal or upper axillary, and supraclavicular.

DIAGNOSIS

The initial workup for a woman presenting with a breast mass or symptoms suggestive of breast cancer should include a careful history, physical examination of the breast, three-dimensional diagnostic mammography, and possibly other breast imaging techniques such as ultrasonography or MRI. Most breast cancers can be visualized on a mammogram as a mass, a cluster of calcifications, or a combination of these findings. One major factor that affects the ability of mammography to detect cancer includes breast density, which may be affected by age, menopausal status, and HRT use. Ultrasonography, MRI, digital mammography, and tomosynthesis are alternate breast imaging methods that are being investigated for women with dense breasts or other specific subsets of patients with breast cancer (eg, MRI in patients with IBC).[14] The technical quality of the examination and the expertise of the radiologist are also important factors affecting reliability.

Breast biopsy is indicated for a mammographic abnormality that suggests malignancy or for a palpable mass on physical examination. Three techniques are available: fine-needle aspiration, core-needle biopsy, and excisional biopsy.[14] Excisional biopsy completely removes the abnormal tissue. Needle biopsies are performed percutaneously and include both core-needle biopsy (which removes a core of tissue) and fine-needle aspiration (which removes cells from the suspicious site). Core-needle biopsy is the preferred biopsy method for mammographically detected, nonpalpable abnormalities.[14] Core-needle biopsy offers a more definitive histologic diagnosis, avoids inadequate samples, and can distinguish invasive from in situ breast cancer (which fine-needle biopsy cannot). After confirmation of malignancy via core-needle biopsy, subsequent surgical procedures are performed (either before or after systemic therapy) to assure complete removal of the abnormal tissue.

PATHOPHYSIOLOGY

The pathologic evaluation of breast tissue serves to establish the histologic diagnosis and to confirm the presence or absence of other factors believed to influence prognosis.

Invasive Carcinoma

Invasive breast cancers are a histologically heterogeneous group of lesions. Most breast cancers are adenocarcinomas and are classified on the basis of their microscopic appearance as ductal or lobular, corresponding to the ducts and lobules of the normal breast (see Fig. 151-1). The various histologic types of breast cancer have different prognoses, but it is unknown whether their response to therapy differs because patients in therapeutic trials are not typically stratified according to histologic type. The five most common types of invasive breast cancer are briefly described below.

Invasive or *infiltrating ductal carcinoma* is the most common histology, accounting for about 75% of all invasive breast cancers. These tumors commonly spread to the axillary lymph nodes, and their prognosis is poorer than for some other histologic types. *Invasive or infiltrating lobular* *carcinoma* accounts for 15% of breast tumors.[2] Both clinical and radiologic findings for these tumors may be quite subtle. The typical presentation is an area of ill-defined thickening in the breast in contrast to a prominent lump characteristic of infiltrating ductal carcinoma (IDC). *Infiltrating lobular carcinoma* (ILC) can also be more difficult to detect by mammography. Overall, ILC and IDC have similar likelihoods of axillary node involvement and disease recurrence and death, but the sites of metastases may differ. While IDC more frequently metastasizes to the bone or to the liver, lung, or brain, ILC tends to metastasize to the leptomeninges, peritoneal surfaces, retroperitoneum, gastrointestinal tract, reproductive organs, and other unusual sites.

The most common special types of invasive cancer are *cribriform*, *mucinous*, *tubular,* and *papillary*. The prognosis may be more favorable with these rare and unusual histologies.[2] Special situations seen clinically and histologically include Paget's disease of the breast, phyllodes tumors, and IBC. Paget's disease of the breast is characterized by neoplastic cells in the nipple areolar complex. The patient presents clinically with eczematous changes in the nipple with itching, burning, oozing, bleeding, or some combination of these. Phyllodes tumors of the breast are rare tumors with subtypes that range from benign to malignant. These tumors often enlarge rapidly, are painless, and can appear as fibroadenomas.[14] IBC is rare, aggressive, and characterized clinically by prominent skin edema, redness and warmth, and induration of the underlying tissue. Biopsies of the involved skin reveal cancer cells in the dermal lymphatics. IBC typically has a rapid onset and is often mistaken for infectious cellulitis or mastitis. The prognosis of patients with IBC is poor even if the disease is apparently localized.[14]

Noninvasive Carcinoma

As with invasive carcinoma, the noninvasive lesions may be divided broadly into ductal and lobular categories. The development of malignancy is a multistep process and invasive breast cancer has a pre-invasive (ie, in situ) phase. During the carcinoma in situ phase, normal epithelial cells undergo genetic alterations that result in malignant transformation. Transformed epithelial cells proliferate and pile up within lobules or ducts but lack the required genetic alterations that enable the cells to penetrate the basement membrane. Carcinoma in situ is diagnosed when malignant transformation of cells has occurred, but the basement membrane is intact.

The widespread use of screening mammography with subsequent biopsy and greater recognition of noninvasive breast carcinoma by pathologists has resulted in a significant increase in the diagnosis of in situ breast cancer. An estimated 49,290 new cases of female noninvasive DCIS were diagnosed in 2021.[1] The natural history of these disorders is not well described, and thus the debate continues whether carcinoma in situ is a pre-invasive cancer or simply a marker of unstable epithelium that represents an increased risk for the development of subsequent aggressive cancer. DCIS is more frequently diagnosed than lobular carcinoma in situ (LCIS). Most cases of DCIS today are found by biopsies performed for clustered microcalcifications seen on screening mammography, a hallmark of this disorder.

Treatment

The ultimate goal of treatment for noninvasive carcinomas is to prevent the development of invasive disease. If left untreated, 15% to 50% of DCIS lesions will progress to invasive breast cancer.[15] Therefore, more than 50% of these tumors do not progress to invasive disease, but identifying this group of patients is not yet possible and all diagnoses should be treated.

Locoregional treatment of DCIS depends on its location, size, and pathology.[14] Treatment options include surgery (mastectomy or lumpectomy), radiation therapy, and adjuvant endocrine therapy if hormone receptor-positive. Axillary lymph node dissection (ALND) is generally not indicated, although sentinel lymph node biopsy (SLNB) (see the "Curative Breast Cancer" section) may be considered in selected patients.[14]

Cytotoxic chemotherapy has no role in the treatment of patients with pure DCIS. It is important to determine hormone receptor status on the cancer cells. Tamoxifen treatment for 5 years may be considered in premenopausal and postmenopausal women with hormone receptor–positive DCIS. Anastrozole for 5 years may also be considered in postmenopausal women with hormone receptor–positive DCIS, particularly if they are less than 60 years.[14]

Unlike DCIS, LCIS is a microscopic diagnosis; generally no palpable mass and no specific clinical abnormality exists. LCIS does not generally demonstrate calcifications on mammography and the diagnosis is usually an incidental finding in biopsy specimens obtained because of symptoms or mammography findings consistent with benign lesions. It is unclear whether LCIS is a precursor lesion or serves as a marker of risk for developing invasive carcinoma in the breast. The 10-year incidence of developing invasive carcinoma is 13.9%.[16] The risk for the development of breast cancer is equally high in either breast, which makes the management of LCIS controversial. Some experts favor a program of observation, with physical examination every 6 to 12 months, annual mammography, and consideration of annual breast MRI or ultrasound.[10] In selected women with high-risk genetic mutations or strong family history and in women who are anxious about the development of cancer, bilateral mastectomies may be considered.[4] Radiation and systemic chemotherapy have no role in the management of LCIS. The use of chemoprevention with tamoxifen in premenopausal women or tamoxifen, raloxifene, anastrozole, or exemestane in postmenopausal women may also be considered for risk reduction (see the "Prevention and Early Detection" section for details).[4] These decisions are often difficult to discuss with patients because these treatments have toxicities. Nonetheless, a discussion regarding the risks and benefits is warranted.

STAGING AND PROGNOSIS

The natural history of breast cancer varies among patients, with some having extremely aggressive disease that progresses rapidly and others following a more indolent course. The ability to predict prognosis is extremely important in designing personalized treatment recommendations. Several pathologic prognostic and predictive factors have been identified. Prognostic factors are characteristics or measurements available at diagnosis or at the time of surgery that in the absence of neoadjuvant or adjuvant systemic therapy are associated with recurrence rate, death rate, or other clinical outcomes. Predictive factors are measurements available at diagnosis that are associated with response to a specific therapy. Prognostic and predictive factors fall into these general categories: (a) patient characteristics that are independent of the disease, such as age; (b) cancer characteristics, such as tumor size or histologic type; (c) other biomarkers that are measurable parameters in tissues, cells, or fluids, such as hormone-receptor status; and (d) genetic variables. The use of prognostic and predictive factors can personalize treatment to patients, increase the likelihood of clinical benefit, and reduce the risk of unnecessary toxicities.

Age at diagnosis and ethnicity can affect prognosis. Some younger patients, particularly those younger than 35 years, have more aggressive forms of breast cancer and a worse prognosis. Younger patients are more likely to present with poor prognostic features, such as affected lymph nodes, large tumor size, and tumors negative for hormone receptors. Black individuals have decreased survival compared with White individuals. The cause of this racial disparity is widely debated, with possible explanations including access to care, socioeconomic status, cultural differences, higher stage at diagnosis, and more aggressive biologic features.

Potentially modifiable prognostic factors include alcohol use, dietary factors, weight, and exercise. Agencies such as the ACS have recognized that physical activity, weight control, and diet are potentially modifiable risk factors for reducing the risk of recurrent breast cancer and other comorbidities (eg, heart disease, diabetes).[17]

Tumor size and the number of involved lymph nodes are established independent factors that influence the risk for breast cancer recurrence and subsequent metastatic disease. The number of affected lymph nodes is directly related to the risk of disease recurrence. The staging system for breast cancer recognizes the absolute number of positive nodes as a prognostic factor (see Table 151-3 for further details).[18] The relationship between tumor size and lymph node status is complex and is not a simple grouping.

TABLE 151-3

Definitions for Tumor, Node, Metastasis

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis (DCIS)	Ductal carcinoma in situ
Tis (Paget)	Paget's disease of the nipple NOT associated with invasive carcinoma or carcinoma in situ
T1	Tumor ≤2 cm in greatest dimension

	T1mi	<0.1 cm; microinvasion
	T1a	>0.1 cm ≤0.5 cm
	T1b	>0.5 cm ≤1 cm
	T1c	>1 cm ≤2 cm
T2	Tumor >2 cm ≤5 cm	
T3	Tumor >5 cm	
T4	Tumor of any size with direct extension to the chest wall and/or to the skin	
	T4a	Extension to the chest wall; invasion or adherence to pectoralis muscle in the absence of invasion of chest wall structures
	T4b	Ulceration and/or ipsilateral macroscopic satellite nodules and/or edema (including peau d'orange) of the skin that does not meet the criteria of inflammatory carcinoma
	T4c	Both T4a and T4b present
	T4d	Inflammatory carcinoma
Regional Lymph Nodes: Clinical (cN)		
cNX	Regional lymph nodes cannot be assessed	
cN0	No regional lymph node metastases	
cN1	Metastases to movable ipsilateral level 1, II axillary lymph node(s)	
	cN1mi	Micrometastases (approximately 200 cells, >0.02 cm <0.2 cm)
cN2	Metastases in ipsilateral level I, II axillary lymph nodes that are clinically fixed or matted; or in ipsilateral internal mammary nodes in the absence of axillary lymph node metastases	
	cN2a	Metastases in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures
	cN2b	Metastases only in ipsilateral internal mammary nodes in the absence of axillary lymph node metastases
cN3	Metastases in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement; or in ipsilateral internal mammary lymph node(s) with level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement	
	cN3a	Metastases in ipsilateral infraclavicular lymph node(s)
	cN3b	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
	cN3c	Metastases in ipsilateral supraclavicular lymph node(s)
Regional Lymph Nodes: Pathologic (pN)		

pNX	Regional lymph nodes cannot be assessed	
pN0	No regional lymph node metastasis identified or ITCs only	
	pN0(i+)	ITCs only, no larger than 0.02 cm in regional lymph nodes
	pN0(mol+)	Positive molecular findings by reverse transcriptase polymerase chain reaction; no ITCs detected
pN1	Micrometastases; or metastases in 1-3 axillary lymph nodes; and/or clinically negative internal mammary nodes with micrometastases or macrometastases by sentinel lymph node biopsy	
	pN1mi	Micrometastases, (approximately 200 cells, >0.02 cm <0.2 cm)
	pN1a	Metastases in ipsilateral internal mammary sentinel nodes, excluding ITCs
	pN1c	pN1a and pN1b combined
pN2	Metastases in 4-9 axillary lymph nodes; or positive ipsilateral internal mammary lymph nodes by imaging in the absence of axillary lymph node metastases	
	pN2a	Metastases in 4-9 lymph nodes (at least one deposit >0.2 cm)
	pN2b	Metastases in clinically detected internal mammary lymph nodes with or without microscopic confirmation; with pathologically negative axillary nodes
pN3	Metastases ≥10 or more axillary lymph nodes; or in infraclavicular (level III axillary) lymph nodes; or positive ipsilateral internal mammary lymph nodes by imaging in the presence ≥1 positive level I, II axillary lymph nodes; or in >3 axillary lymph nodes and micrometastases or macrometastases by sentinel lymph node biopsy in clinically negative ipsilateral internal mammary lymph nodes; or in ipsilateral mammary lymph nodes	
	pN3a	Metastases in ≥10 axillary lymph nodes (at least one tumor deposit >0.2 cm) or metastatses to infraclavicular (level III axillary lymph) nodes
	pN3b	pN1a or pN2a in the presence of cN2b (positive internal mammary nodes by imaging) or pN2a in presence of pN1b
	pN3c	Metastases in ipsilateral supraclavicular lymph nodes
Distant Metastasis (M)		
M0	No clinical or radiographic evidence of distant metastases	
	cM0(i+)	No clinical or radiographic evidence of distant metastases in the presence of tumor cells or deposits <0.02 cm detected microscopically or by molecular techniques in circulating blood, bone marrow, or other nonregional nodal tissue in a patient without symptoms or signs of metastases
cM1	Distant metastases detected by clinical and radiographic means	
pM1	Any histologically proven metastases in distant organs; or if in nonregional nodes, metastases >0.02 cm	

ITCs, isolated tumor cells.

Reproduced, with permission, from Hortobagyi GN, Connolly JL, D'Orsi CJ, et al. Breast. In: Amin EB, Edge SB, Gress DM, et al., AJCC Cancer Staging Manual. 8th Ed. Chicago, IL: Springer. 2017:589–638.

Certain histologic subtypes and clinical presentation of breast cancer have prognostic importance. As mentioned earlier, treatment recommendations may differ because women with pure *tubular* or *mucinous* tumors have more favorable outcomes than those with *invasive ductal carcinomas*.[14] IBC, a clinical designation and not a distinct histologic subtype, is associated with a poor prognosis.[14]

Nuclear grade and tumor (histologic) differentiation are also independent prognostic indicators. Several histologic grading systems have been developed, most of which grade tumors with a score from 1 to 3: grade 1, well differentiated; grade 2, moderately differentiated; and grade 3, poorly differentiated. Grading is incorporated as part of the staging system (see Table 151-4 for details regarding grading).[18] Higher grade tumors are associated with higher rates of distant metastasis and poorer survival. This factor aids in making treatment decisions, particularly for patients with small tumors and negative lymph nodes. Additional factors may include lymphovascular invasion and proliferation indices.

Hormone receptors are not strong prognostic markers but are used clinically to predict responses to endocrine therapy. Determination of both ER and PR status is an established procedure that is important in the management of breast cancer. Most patients with primary or MBC have hormone receptor–positive tumors. Hormone receptor positivity, more common in postmenopausal individuals, is associated with a higher response to endocrine therapy and longer disease-free survival.

The *HER2* protein is normally expressed at low levels in the epithelial cells of normal breast tissue. *HER2* overexpression occurs in about 15% to 20% of breast cancers and is associated with increased tumor aggressiveness, increased rates of recurrence, and increased mortality rates.[2,19] *HER2* overexpression is associated with poor prognosis and is measured by fluorescence in situ hybridization (FISH) and immunohistochemistry (IHC). Tumors that are either IHC 3+ or FISH positive are considered to be positive for *HER2*.[14] *HER2*-positive status clearly predicts response to *HER2*-targeted therapy. Patients with *HER2*-positive MBC treated with trastuzumab, a monoclonal antibody (mAb) directed against the extracellular domain of the *HER2* receptor, have improved survival rates compared to patients with *HER2*-negative MBC or patients with *HER2*-positive MBC who do not receive trastuzumab.

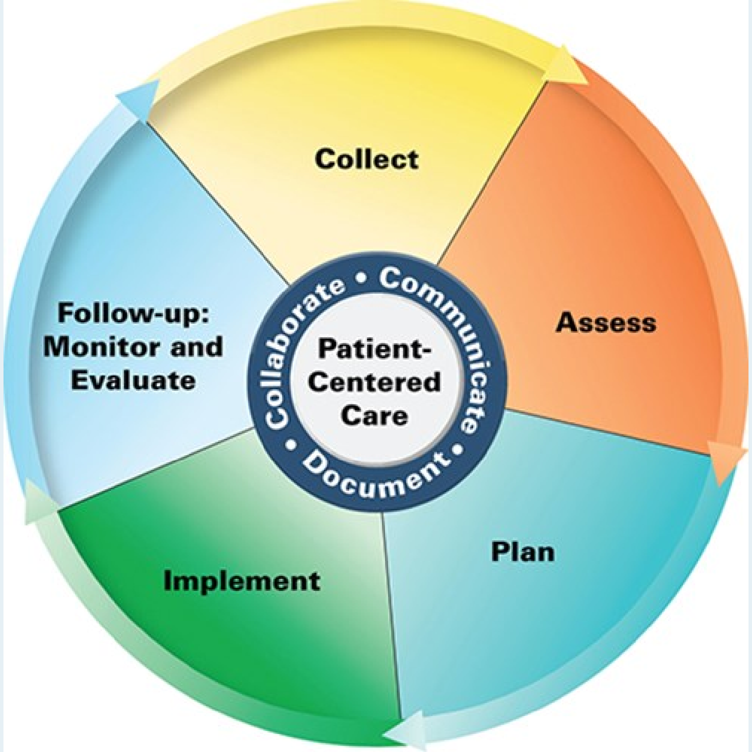
Genetic profiling is also being used to provide prognostic and predictive information on clinical outcomes of breast cancer.[14] Further details on these assays are available in the "Genomic Testing" section under Curative Breast Cancer.

Breast cancer stage is based on the primary tumor extent and size, presence and extent of lymph node involvement, and presence or absence of distant metastases (Fig. 151-2, Tables 151-3 and 151-4). Although many possible combinations of T and N are possible within a given stage, simplistically, stage 0 represents carcinoma in situ (Tis) or disease that has not invaded the basement membrane of the breast tissue. Stage I represents a small primary invasive tumor without lymph node involvement or with micrometastatic nodal involvement, and stage II disease usually involves regional lymph nodes. Stages I and II are often referred to as *early breast cancer*. It is in these early stages that the disease is highly curable (99% 5-year survival in patients with disease confined to the breast, node negative).[2] Stage III, also referred to as *locally advanced disease*, usually represents a large tumor with extensive nodal involvement in which either node or tumor is fixed to the chest wall. A wide variety of clinical scenarios can be seen within this group of patients, including neglected tumors that have spread locally to IBCs that are a unique clinical entity. IBC is associated with similar clinical findings compared with neglected, locally advanced breast tumors (eg, erythema representing skin involvement). The distinction between the two diagnoses lies in the rapidity of onset of symptoms. Many locally advanced breast cancers are diagnosed in patients who have had symptoms for months to years and have neglected to seek medical attention. Although these women have a poor prognosis because of the delay in diagnosis, they are not classified as IBC. Stage IV disease is characterized by the presence of metastases to organs distant from the primary tumor and is often referred to as *advanced or metastatic disease* as described earlier (27% 5-year survival rate in patients with distant metastases).[2] Most individuals with breast cancer in the United States present in early stages where the prognosis is favorable (91% of newly diagnosed patients have disease confined to the breast or local lymph nodes).[2]

Staging for breast cancer is separated into clinical and pathologic staging. Clinical stage is assigned before surgery and is based on physical examination (assessment of tumor size and presence of axillary lymph nodes), imaging (eg, mammography, ultrasonography), and pathologic examination of tissues (eg, biopsy results). Pathologic staging occurs after surgery and adds data from surgical exploration and resection. The American Joint Committee for Cancer (AJCC), publishes staging criteria for cancers.

PATIENT CARE PROCESS

Patient Care Process for Breast Cancer



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, biological sex)
- Physical examination, including clinical breast examination (if appropriate) and general examination to evaluate for MBC
- Patient medical history (personal and family history for breast and ovarian cancers, start of menstruation, time of menopause, surgical history [eg, hysterectomy, oophorectomy])
- Social history (eg, tobacco/ethanol use) and dietary habits
- Current medications including OTC use, herbal products, birth control, and dietary supplements
- Objective data
    - Height, weight

  - Laboratory findings including complete blood count with differential, SCr, total bilirubin, AST, ALT, alkaline phosphatase
  - Staging
  - Tumor genomics if appropriate (eg, Oncotype DX, MammaPrint, Prosigna). For other details, see "Genomic Testing" under Systemic Therapy section
  - For other details, see section "Clinical Presentation"

Assess

- Comorbidities
- Current medications and medication adherence
- Ability/willingness to pay for treatment options, insurance coverage
- Emotional status (eg, presence of anxiety, depression)
- Type of and response to prior treatment(s) and need for dose reductions and/or supportive care
- For other details, see section "Clinical Presentation"

Plan*

- Drug therapy regimen including specific chemotherapy, endocrine therapy, or targeted therapy and include dose, route, frequency, duration, and supportive care (see Fig. 151-3, Tables 151-5–151-8 and 151-10 in "Curative Breast Cancer" and "Metastatic Breast Cancer" sections)
- Monitoring parameters including efficacy (eg, staging studies such as CT chest, abdomen/pelvis, bone scan, CT/MRI brain in the cases of metastatic disease; ultrasound in the cases of neoadjuvant therapy), adverse drug reaction management (eg, nausea/vomiting, mucositis, neutropenia, hot flashes, myalgias), and safety (eg, CBC with differential, SCr, total bilirubin, AST/ALT, DEXA scan for bone health); frequency and timing of follow-up
- Patient education (eg, goal of treatment, dietary and lifestyle modification, drug-specific information; see "Curative Breast Cancer" and "Metastatic Breast Cancer" sections and Table 151-9)
- Self-monitoring for resolution of nausea/vomiting, mucositis, fever, when to seek emergency medical attention
- Referrals to other providers when appropriate (eg, dietician, supportive care services, psychiatry, bone health, cardiology, genetics)

Implement*

- Provide patient education regarding all elements of the treatment plan. If patient has completed curative therapy, review survivorship care plan (ie, frequency of clinic visits)
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, labs, staging scans, monitoring tests [eg, ECHO/MUGA, DEXA scan, ultrasound])

Follow-up: Monitor and Evaluate

- Resolution of adverse drug reactions (eg, nausea/vomiting, mucositis, myalgia)
- Presence of adverse drug reactions (eg, constipation, diarrhea)
- Patient adherence to treatment plan using multiple sources of information

- Re-evaluate duration of therapy, depending on specific regimen

Collaborate with patient, caregivers, and other healthcare professionals.

TREATMENT

Curative Breast Cancer (Stage I-III)

Desired Outcomes

In the curative setting, through the use of different modalities of treatment—surgery, radiation, and systemic therapy, the desired outcome is cure of disease. This differs significantly from the desired outcomes when treating metastatic disease. Locoregional and systemic therapy and their roles in curing breast cancer are discussed below. While the desired outcome is the same for patients with stage I-III breast cancer, the terminology and sequence of therapies may differ. For example, *locally advanced breast cancer (stage III)* generally refers to breast carcinomas with significant primary tumor and nodal disease but in which distant metastases cannot be documented. In this setting, neoadjuvant systemic therapy may be administered to decrease tumor size prior to surgery and/or to allow for breast conserving surgery if desired by the patient. This approach to systemic therapy also allows for assessment of response to therapy. In contrast, the intent of adjuvant systemic therapy is to eradicate micrometastatic disease. A predetermined number of cycles or duration of systemic therapy is given in the neoadjuvant and adjuvant settings. Clinicians and patients must weigh the short and long-term effects of systemic therapy against the benefits of lowering the risk of breast cancer recurrence.

Locoregional Therapy

③ Most patients presenting with breast cancer have an *in situ* tumor (stage 0), a small invasive tumor with negative lymph nodes (stage I), or a small invasive tumor with axillary lymph node involvement (stage II). Surgery alone can cure most, if not all, patients with in situ cancers: 70% to 80% of patients with stage I and about half of patients with stage II cancers. The choice of surgical procedures has changed drastically over the past 50 years, which is related to an increased understanding of the biology of breast cancer and the results of a series of well-conducted clinical trials performed over this time period.

Most patients diagnosed with breast cancer can be treated with BCT, a less extensive surgery than mastectomy (complete removal of the breast) that maintains acceptable cosmetic results and rates of local and distant recurrence and mortality.[14] BCT includes removal of part of the breast, surgical evaluation of the axillary lymph node basin, and radiation therapy to the breast. The amount of breast tissue removed as a part of BCT varies from removing the cancerous "lump" (ie, lumpectomy) with a small margin of adjacent normal-appearing tissue to removing the "lump" with a wider excision of adjacent normal-appearing tissue (ie, wide local excision) to removing the entire quadrant of the breast that includes the cancerous "lump" (ie, quadrantectomy). All these techniques are referred to as segmental or partial mastectomy. Overall survival rates are similar to BCT compared with mastectomy; however, a small increase in the risk of locoregional recurrence occurs with BCT.[14]

Several factors should be considered in selecting patients for BCT, such as younger age, family history, and genetic predisposition. The NCCN guidelines recommend that women who carry a known *BRCA1* or *BRCA2* mutation undergo mastectomy and consider additional risk reduction strategies (eg, bilateral mastectomies).[6] Bilateral total mastectomy and oophorectomy reduce the risk of breast cancer recurrence in patients with *BRCA1* or *BRCA2* mutations. Multiple sites of cancer within the breast and the inability to attain negative pathologic margins on the excised breast specimen are indications for mastectomy. Other relative contraindications may need to be considered when making the decision for the type of surgery. Local recurrence after BCT has not been consistently associated with an increased mortality rate, but it can be distressing to the patient and requires surgical removal of the remaining breast tissue. Other considerations include previous radiation to the breast, expected cosmetic result, and extent of local disease. The availability of an external-beam radiation facility and the patient's willingness to comply with the prescribed course of radiotherapy must also be considered. Radiotherapy after BCT reduces the 10-year risk of first recurrence by 16% and the 15-year risk of breast cancer death by 4% as compared with no radiotherapy.[14] External-beam radiation therapy after BCT usually involves 3 to 5 weeks of radiation therapy directed to the entire breast tissue to eradicate residual disease. Local tumor control is similar with shorter courses versus longer courses of radiation, and toxicities, such as breast shrinkage, telangiectasias, and breast edema are less common with shorter regimens. The NCCN guidelines recommended radiation course is 40 to 42.5 Gy in 15 to 16 fractions or 46 to 50 Gy in 23 to 25 fractions.[14] Complications associated with radiation therapy to the breast are generally minor and include reddening and erythema of the breast tissue and subsequent shrinkage of the total breast mass beyond that predicted on the basis of breast tissue removal.

Postmastectomy radiation therapy to the chest wall and regional lymph nodes (if indicated) may also be required in certain situations when tumors are large or the number of positive axillary lymph nodes is high. Post-mastectomy radiation is recommended for patients with ≥ 4 positive axillary lymph nodes and should be considered in situations where the tumor is ≤ 5 cm with negative axillary lymph nodes and margins <1 mm, the tumor is >5 cm with negative lymph nodes, 1 to 3 lymph nodes are positive, and if there are positive margins.[14]

The optimal sequence of radiation therapy and chemotherapy is somewhat controversial, but it is common to begin radiation after completion of chemotherapy when chemotherapy is recommended. If chemotherapy is not indicated, radiation is administered after surgery (see the "Biologic or Targeted Therapy" section under Curative Breast Cancer for a discussion of sequencing trastuzumab).

Accurate assessment of the spread of breast cancer cells to the axillary lymph nodes is critical for prognosis and personalizing local and systemic treatments. The number of positive axillary lymph nodes remains the most powerful predictor of breast cancer recurrence and survival, but other benefits may include a therapeutic effect of removing the lymph nodes and obtaining information to guide treatment selection. However, axillary dissection is associated with significant morbidity, including lymphedema, arm pain or numbness, and reduced quality of life.[14] About 60% of patients with early-stage breast cancer (ESBC) present with lymph node–negative disease, which indicates that many women would derive no therapeutic benefit but would be exposed to the complications from the full ALND.

For these reasons, a procedure involving lymphatic mapping and SLNB is recommended for patients with clinically negative lymph nodes.[20] The sentinel lymph node(s) is the first lymph node(s) that receives lymph drainage from the primary tumor. Injection of a vital blue dye, a radiocolloid, or both, around the primary breast tumor identifies the sentinel lymph node(s) in most patients, and the status of this lymph node(s) predicts the status of the remaining nodes in the nodal basin. Patients with lymph nodes that are suspicious for cancer involvement either by physical examination or imaging should have a biopsy performed to exclude lymph node involvement.[14] Historically, patients with positive sentinel nodes have proceeded to a level I and II ALND. However, ALND after SLNB in women with clinically node-negative tumors smaller than 5 cm, fewer than three involved sentinel lymph nodes, and undergoing BCT with subsequent breast irradiation results in higher morbidity, no improvement in local recurrence, and no difference in disease-free or overall survival as compared with SLNB alone.[21] Therefore, the ASCO and NCCN guidelines do not recommend ALND for women with ESBC with one or two positive sentinel lymph nodes who will receive BCT followed by radiation.[14,20] Women undergoing mastectomy with positive sentinel lymph nodes should be offered ALND.

Systemic Therapy

As stated previously, the desired therapeutic outcome of curative systemic therapy for breast cancer differs significantly from that of metastatic disease. Systemic therapy— chemotherapy, biologic or targeted therapy, and endocrine therapy— in this setting is administered with curative intent. For patients with inflammatory or locally advanced/unresectable breast cancer, neoadjuvant chemotherapy is considered the treatment of choice.[22]

Genomic Testing

Intensive research efforts have been directed toward identifying characteristics of the primary tumor (eg, pathologic or molecular prognostic factors) that may predict for a higher or lower likelihood of distant metastases and death in node-negative patients. Although many prognostic factors continue to be investigated, no single factor or combination of factors sufficiently identifies those at risk of metastases or is sufficiently standardized to be reproducibly applicable to all patients. Several multigene expression assays are commercially available as decision-support tools for adjuvant chemotherapy.[23] Oncotype DX® is one test that screens for expression of 21 genes with reverse transcription polymerase chain reaction (RT-PCR), and reports a recurrence score that correlates with the risk of distant recurrence or death from breast cancer in women with ER-positive, node-negative, invasive breast cancer. This test was initially validated in node-negative invasive breast cancer. A low recurrence score (≤ 15) indicates a low risk of recurrence with endocrine therapy alone indicating that perhaps adjuvant chemotherapy could be avoided. A high recurrence score (≥26) indicates a high risk of recurrence despite endocrine therapy, suggesting a need for adjuvant chemotherapy followed by endocrine therapy. For premenopausal patients with a score of 16 to 25, chemotherapy followed by endocrine therapy may be considered.[14,24] Postmenopausal patients with ER-positive, node-positive (1-3 positive lymph nodes) with a recurrence score of < 26 may receive only endocrine therapy in the adjuvant setting. Premenopausal patients with a risk score less than 26 may derive benefit from chemotherapy followed by endocrine therapy and should be considered based on other factors. Patients with 1 to 3 positive lymph nodes and a recurrence score of ≥ 26 should be offered chemotherapy regardless of menopausal status.[14] Other commercially available multigene assays include MammaPrint® and Prosigna®. MammaPrint® screens the tumor for 70 genes with microarray technology in breast cancer patients with ESBC, regardless of hormone-receptor status. The assay reports the predicted rates of recurrence as high or low. PAM50 (Prosigna®) is a multigene test that screens the tumor for 50 genes (plus 5 control genes) to predict distant relapse-free survival and likelihood of recurrence at 10 years in postmenopausal women with ER-positive breast cancer treated with endocrine therapy regardless of nodal status.[23]

Cytotoxic Chemotherapy

Systemic adjuvant therapy is defined as the administration of systemic therapy after definitive local therapy (surgery, radiation, or both) when there is no evidence of metastatic disease but a high likelihood of disease recurrence. By the time breast cancers become clinically detectable, they have likely been present for a number of years and have had an opportunity to establish distant micrometastases. Micrometastatic disease can travel from the primary breast tumor and spread to distant organs through several different routes (eg, hematogenous spread through blood vessels, lymphangitic spread through lymph channels, local extension to surrounding structures). Local therapies, such as breast surgery and irradiation, do not eradicate distant micrometastases; therefore, systemic therapy is required to target these tumor cells that may have escaped the local area of the breast. The risk of micrometastatic disease is one factor used to identify patients with a high risk of recurrence who would require systemic adjuvant therapy. Chemotherapy, endocrine therapy, targeted therapy, or some combination of these agents improves disease-free and/or overall survival for high-risk patients in specific prognostic subgroups (eg, nodal involvement, menopausal status, hormone-receptor status, or *HER2* status) based on the results of several hundred randomized clinical trials.

The benefit of adjuvant chemotherapy has been studied and established through several clinical trials over the years. With the evolution of chemotherapy regimens to the current standard, disease-free survival is increased with the addition of chemotherapy regardless of ER/PR status. A 12.4% increase in 5-year disease free survival is seen when taxanes are added to anthracycline chemotherapy.[25] Five-year overall survival is increased with the addition of chemotherapy, but longer follow-up may be needed to solidify this benefit. Adjuvant chemotherapy is recommended in most women with lymph node metastases or with primary breast cancers larger than 1 cm in diameter (both node-negative and node-positive).[29]

⑥ Several international and national groups have developed guidelines for the treatment of ESBC based on specific patient and disease characteristics and as newer data are available. The four most commonly referenced guidelines are the St. Gallen International Expert Consensus Conference, European Society of Medical Oncology, or ESMO, the American Society of Clinical Oncology (ASCO), and the NCCN guidelines.[14,26–28] These guidelines are updated annually to every 2 years or more frequently based on available evidence. Recommendations from the NCCN guidelines for patients with tumors 1 cm or larger or positive lymph nodes are summarized in Fig. 151-3. For patients with tumors smaller than 1 cm, micrometastatic lymph node involvement, or negative lymph nodes, treatment is highly individualized and based on multiple patient- and tumor-related factors, including hormone-receptor status, *HER2* status, comorbidities, and patient preferences. Specific treatment recommendations are complex and readers are referred to the guidelines for further details.

[a] Oncotype DX® may identify patients who derive little benefit from chemotherapy (see the "Genomic Testing" section under Curative Breast Cancer

for details). (HR, hormone receptor; *HER2*, human epidermal growth factor receptor-2.)

⑦ The use of neoadjuvant systemic therapy is the standard of care for patients with locally advanced breast cancer and IBC and represents an important treatment option for patients with ESBC. This approach to therapy usually consists of chemotherapy, either alone or combined with biologic or targeted therapy, but in special circumstances may also include endocrine therapy (eg, in inoperable patients with significant comorbidities or in tumors with high sensitivity to endocrine therapy). Advantages of preoperative systemic therapy include a decrease in tumor size to minimize surgery, determination of response to chemotherapy or hormone therapy (an important prognostic indicator), and other theoretical advantages (eg, delivery of chemotherapy through an intact vascular system). Preoperative chemotherapy has similar disease-free or overall survival rates compared with adjuvant chemotherapy (the same chemotherapy and the same number of cycles), but is associated with higher rates of BCT.[14] Patients who receive neoadjuvant chemotherapy may experience a pathological complete response (defined as no tumor left at surgery [pCR]) after chemotherapy. Patients who achieve a pCR have a significantly longer disease-free and overall survival compared to patients who do not achieve a pCR.[14] The use of preoperative systemic therapy in patients with ESBC is generally recommended because of the ability to assess the response to therapy as well as the potential to decrease the size of the tumor, allowing for less radical surgery and better cosmetic results.

The most common cytotoxic drugs that have been used alone and in combination as adjuvant therapy for breast cancer include doxorubicin, epirubicin, cyclophosphamide, methotrexate, fluorouracil, carboplatin, paclitaxel, and docetaxel. Combination chemotherapy regimens (polychemotherapy) are more effective than single-agent chemotherapy. Table 151-5 lists the most common combination chemotherapy regimens used.

TABLE 151-5

Selected Neo/Adjuvant Chemotherapy Regimens for Breast Cancer

Dose-Dense AC → Paclitaxel[a]	**AC → Paclitaxel**
Doxorubicin 60 mg/m^2 IV bolus, day 1	Doxorubicin 60 mg/m^2 IV, day 1
Cyclophosphamide 600 mg/m^2 IV, day 1	Cyclophosphamide 600 mg/m^2 IV, day 1
Repeat cycles every 14 days for 4 cycles (must be given with growth factor support)	Repeat cycles every 21 days for 4 cycles

Data from Reference 14.

Anthracyclines (doxorubicin or epirubicin) and taxanes (paclitaxel or docetaxel) have become the cornerstones of modern chemotherapy for the adjuvant treatment of breast cancer. Anthracycline-containing chemotherapy regimens decrease the 10-year risk of recurrence from 47% to 39% and 10-year overall mortality from 40% to 35%. As mentioned previously, the addition of taxanes to anthracycline-based chemotherapy has a modest added benefit in disease-free survival.[25,29] Proportional reductions in recurrence and breast cancer mortality were largely independent of age, nodal status, tumor size, tumor differentiation, or ER status. Most of these trials enrolled node-positive patients only, but some high-risk node-negative patients were also included.[29,30]

Cytotoxic chemotherapy is a particularly important treatment modality for patients with tumors that do not express ER or PR and do not overexpress *HER2* (often referred to as triple-negative breast cancer [TNBC]).[31] TNBC represents an uncommon subtype (10%-15%) and has a relatively poor prognosis.[32] Patients with TNBC treated with anthracycline- and taxane-based chemotherapy have significantly decreased survival compared to patients with other breast cancer subtypes. Ironically, this patient subgroup is more likely to respond to neoadjuvant chemotherapy. Furthermore, patients with TNBC who achieve a pCR have excellent long-term survival, but those who have residual disease at the time of surgery have a worse prognosis than non-TNBC patients. The optimal type and duration of chemotherapy for patients with TNBC is unknown. More recently, the addition of carboplatin to a neoadjuvant anthracycline- and taxane-based chemotherapy regimen resulted in a higher pCR rate as compared to chemotherapy without carboplatin, but with increased toxicity.[31] Identification of actionable molecular targets for this aggressive breast cancer subtype is needed and ongoing (eg, EGFR and poly-ADP ribose polymerase [PARP]). Adjuvant capecitabine for 6 to 8 cycles may be offered because it improves disease-free and overall survival as compared to those who did not receive additional chemotherapy.[33]

Although the optimal duration of chemotherapy administration is unknown, it takes between 12 and 24 weeks and depends on the regimen being used. Optimally, chemotherapy should be initiated within 12 weeks of surgical removal of the primary tumor.[34] “Dose intensity” and “dose density” are critical factors in achieving optimal outcomes in adjuvant breast cancer therapy. *Dose intensity* is defined as the amount of drug administered per unit of time and is typically reported in milligrams per square meter of body surface area per week (mg/m^2/week). Increasing dose, decreasing time between doses, or both can increase dose intensity. *Dose density* is one way of achieving dose intensity but not by increasing the amount of drug given, as occurs with dose escalation, but instead by decreasing the time between treatment cycles. Dose reductions for standard treatment regimens should be avoided unless necessitated by severe toxicity. Increasing doses beyond those contained in standard treatment regimens does not appear to be beneficial and may be harmful.

The short-term toxicities of chemotherapy used in the adjuvant setting are generally well tolerated. Supportive therapy of patients receiving systemic adjuvant chemotherapy has improved over the past decades. More effective antiemetics have become available to manage chemotherapy-induced nausea and vomiting, and myeloid growth factors can prevent febrile neutropenia, particularly in elderly patients and patients receiving dose-dense chemotherapy regimens. The use of myeloid growth factors to support some adjuvant chemotherapy regimens may be required (eg, with dose-dense regimens), but these are not routinely used with adjuvant chemotherapy regimens. Many other adverse drug reactions are common with the chemotherapy regimens used for the treatment of ESBC, and patients should be appropriately counseled regarding the likelihood of alopecia, weight gain, fatigue, peripheral neuropathy, and myelosuppression. Patients who are menstruating often experience a cessation of menses that may not return; cessation of menses may be accompanied by signs and symptoms of menopause. Leukemia and other hematologic disorders have long been associated with the alkylating agents (eg, cyclophosphamide) and the topoisomerase II inhibitors (eg, doxorubicin and epirubicin; see Chapter 150, “Supportive Care” for more information).

Cardiomyopathy induced by doxorubicin occurs in fewer than 1% to 2% of individuals whose total dose of anthracycline is less than 300 mg/m^2 of doxorubicin equivalents.[35] This risk may be further decreased by the use of continuous infusion or weekly doxorubicin. It should be noted that epirubicin in the adjuvant setting is usually given at a dose of 100 mg/m^2.[14] At this dose, epirubicin has an equal risk of cardiomyopathy as standard doxorubicin doses when both agents are given as bolus or short infusions. Taxanes are often associated with hypersensitivity reactions, peripheral neuropathy, or myalgias and arthralgias for a few days after the infusion.

It is currently not possible to accurately predict who will attain this survival benefit. Genetic prognostic tools, such as Oncotype DX®, can help to identify patients who may derive little or no benefit from chemotherapy. However, these tests are only appropriate in specific subsets of patients. Many adjuvant chemotherapy regimens are available, but most of these regimens have not been directly compared in randomized clinical trials. NCCN guideline recommendations are purposefully vague, and they do not differentiate between patients with node-positive or -negative breast cancer. The NCCN guidelines have designated preferred chemotherapy regimens, as listed in Table 151-5, although detailed information is not provided regarding the rationale behind these designations.

Biologic or Targeted Therapy

Therapies directed at molecular targets through novel mechanisms are often referred to as targeted therapy. Many of the targeted therapies are also biologic therapies because they are mAbs. Trastuzumab is a mAb targeted against the *HER2*-receptor protein. Trastuzumab in combination with or sequentially after adjuvant chemotherapy is recommended for patients with early-stage, *HER2*-positive breast cancer, resulting in a 48% reduction in the risk of recurrence as well as superior disease-free and overall survival, compared with chemotherapy alone (Table 151-6).[14] Although the benefit of adding trastuzumab to these regimens is clear, the optimal trastuzumab-based regimen is less clear because the type of chemotherapy, sequence of administration, and duration of trastuzumab differed among the trials.

TABLE 151-6

Selected Regimens for HER2-Positive Early-Stage Breast Cancer

Neo/Adjuvant Regimen	Drugs	Doses	Frequency	Cycles
PH → H[a]	Paclitaxel	80 mg/m^2 IV over 1 hour	Every 7 days	12 weeks
	Trastuzumab	4 mg/kg IV → 2 mg/kg IV	Every 7 day	12 weeks
	Followed by			
	Trastuzumab	6 mg/kg IV	Every 21 days	Complete 1 year
TCH[a]	Docetaxel	75 mg/m^2 IV	Every 21 days	6
	Carboplatin	AUC 6 IV	Every 21 days	6
	Trastuzumab	4 mg/kg IV → 2 mg/kg IV	Every 7 days	18 weeks
	Followed by			
	Trastuzumab	6 mg/kg IV	Every 21 days	Complete 1 year
TCHP[a]	Docetaxel	75 mg/m^2 IV	Every 21 days	6
	Carboplatin	AUC 6 IV	Every 21 days	6
	Trastuzumab	8 mg/kg IV → 6 mg/kg IV	Every 21 days	6
	Pertuzumab	840 mg IV → 420 mg IV	Every 21 days	6
	Followed by			
	Trastuzumab	6 mg/kg IV	Every 21 days	Complete 1 year
	Pertuzumab	420 mg IV	Every 21 days	Complete 1 year

PH (paclitaxel, trastuzumab); TCH (docetaxel, carboplatin, trastuzumab); TCHP (docetaxel, carboplatin, trastuzumab, pertuzumab);

[a] Designated as a preferred regimen in the NCCN Breast Cancer Guidelines.

Data from Reference 14.

Most of the regimens investigated in these adjuvant trials included an anthracycline and a taxane given concurrently with trastuzumab or sequentially before trastuzumab. Administration of a taxane with trastuzumab may be more effective than trastuzumab administered after chemotherapy. Sequential and concomitant use of trastuzumab with chemotherapy prolongs disease-free survival as compared with chemotherapy alone. Concomitant trastuzumab also improves overall survival, but sequential trastuzumab does not.[14] The adjuvant use of trastuzumab without an anthracycline provides similar benefit with diminished cardiac adverse drug reactions as compared with traditional anthracycline-containing adjuvant trastuzumab regimens.[14] The optimal duration of trastuzumab therapy is unknown, although the majority of data support the use of trastuzumab for a total of 52 weeks (range, 9-104 weeks). The most commonly used trastuzumab-based neo/adjuvant chemotherapy regimens are listed in Table 151-6.

The addition of mAb pertuzumab is another important treatment option for patients with *HER*2-positive breast cancer in the neoadjuvant setting.[36] The addition of pertuzumab to trastuzumab and chemotherapy produces high rates of pCR at the time of surgery in patients with tumors larger than 2 cm or positive lymph nodes (see Table 151-6 for details regarding the most commonly used regimens). Additionally, an approximately 1% absolute benefit in invasive disease-free survival at 3 years that continues for at least 6 years as well as an improvement in overall survival can occur with the addition of pertuzumab. The FDA added an indication for pertuzumab in combination with trastuzumab in the adjuvant setting for high-risk *HER2*-positive breast cancer based on this trial.[37] A newer formulation containing pertuzumab, trastuzumab, and hyaluronidase-zzxf injection for subcutaneous use is approved for the treatment of *HER2*-positive breast cancer in all settings.[38]

The incidence of adverse cardiac drug reactions associated with the addition of trastuzumab increases when an anthracycline is included in the regimen before administration of trastuzumab. The risk of symptomatic heart failure with adjuvant trastuzumab ranges from 0.5% to 4%.[39] The higher risk of cardiac complications may be acceptable in many patients, given the significant reductions in breast cancer recurrence and death. Sequential administration of trastuzumab after chemotherapy produces a lower incidence of cardiac toxicity. Also, the use of a non-anthracycline–based regimen (see Table 151-6) is associated with a low incidence of symptomatic heart failure as compared with other regimens.[14] Concurrent administration of trastuzumab with an anthracycline is controversial because of potentially higher rates of cardiac dysfunction (see the "*HER2-Targeted Agents*" section under MBC (Stage IV) for more toxicity details) and not generally recommended outside of a clinical trial.

Patients who received concurrent radiation therapy with adjuvant trastuzumab do not experience a significant increase in cardiac events or acute radiation-related adverse drug reactions.[40] Therefore, if radiation therapy is clinically indicated, trastuzumab is typically administered concomitantly with radiation.

Many questions remain regarding the optimal use of trastuzumab in the adjuvant or neoadjuvant therapy of ESBC. The use of trastuzumab with chemotherapy in the adjuvant or neoadjuvant setting is now considered to be the standard of care for patients with node-positive and high-risk node-negative *HER2*-positive breast cancer.[14] The use of *HER2*-targeted therapy in patients with small, *HER2*-positive, node-negative tumors is controversial. A single arm, nonrandomized clinical trial demonstrated an excellent 3-year disease-free survival (98.7%) in patients who received weekly paclitaxel and trastuzumab for 12 weeks, followed by trastuzumab every 3 weeks for a total of 1 year in patients with lymph-node negative, *HER2*-positive, breast cancers smaller than 3 cm.[41] Seven-year follow up data reported disease-free survival of 93% and an overall survival of 97% which confirms the benefit of this regimen in small, *HER2*-positive, node negative tumors.[42] The NCCN guidelines recommend consideration of this regimen for patients who have pathologic T1N0M0 *HER2*-positive breast cancer.[14] Neratinib (240 mg by mouth daily for 1 year), an oral tyrosine kinase inhibitor of EGFR, *HER2*, and *HER4*, is indicated for extended adjuvant therapy after completion of trastuzumab (within previous 2 years) based on small improved disease-free survival. The most common adverse drug reactions of neratinib include diarrhea, which requires aggressive management, as well as nausea, fatigue, and vomiting. Neratinib may be an option for extended adjuvant therapy in some patients at higher risk of recurrence.[43]

The use of ado-trastuzumab emtansine (also known as T-DM1) in the adjuvant setting following neoadjuvant therapy when residual disease is found at the time of surgery is the standard of care because it improves invasive disease-free survival at 3 years compared with trastuzumab (88% vs 77%).[14,44] Patients should be counseled on adverse drugs reactions of ado-trastuzumab emtansine that are different than trastuzumab. Ado-trastuzumab emtansine is associated with peripheral neuropathy, thrombocytopenia, and liver dysfunction.

Endocrine Therapy

⑤ Endocrine therapies that have been studied in the treatment of primary or early-stage breast cancer include tamoxifen, toremifene, oophorectomy, ovarian irradiation, luteinizing hormone–releasing hormone (LHRH) agonists, and AIs. The choice of agent(s) depends on menopausal status of the individual.

If chemotherapy and radiation therapy are not indicated, adjuvant endocrine therapy is generally initiated shortly after surgery or as soon as pathology results are known. When adjuvant chemotherapy is also indicated, endocrine therapy should be administered after chemotherapy is completed.[14] Some clinicians also recommend the initiation of endocrine therapy after completion of radiation therapy, but this recommendation is controversial because few trials have addressed the issue of concurrent versus sequential endocrine therapy and radiation therapy.

Tamoxifen is historically considered as the gold standard adjuvant endocrine therapy and has been used in this setting for several decades. Tamoxifen is antiestrogenic in breast cancer cells, but it has estrogenic properties in other tissues and organs.[45] More recent studies show that tamoxifen, and other similar drugs, have many estrogenic and antiestrogenic effects that depend on the tissue and the gene in question, and they are more appropriately considered SERMs. Women receiving adjuvant tamoxifen therapy have reduced risk of recurrence and mortality compared with women not receiving adjuvant tamoxifen therapy.[45] In the United States, tamoxifen is generally considered the adjuvant endocrine therapy of choice for premenopausal women, although newer data also support the use of LHRH agonists or oophorectomy in combination with AIs.

The pharmacologic disposition of tamoxifen in humans is complex (see Fig. 151-4). Tamoxifen is considered a prodrug. Although the parent compound has significant clinical activity, tamoxifen is metabolized through multiple enzymes, including cytochrome P450 (CYP)3A4, CYP2C19, CYP2D6, and others, to metabolites that are more active than the parent compound.[45] The active metabolites 4-hydroxytamoxifen (4OH-tamoxifen) and 4-hydroxy-*N*-desmethyltamoxifen (endoxifen) have nearly a 100-fold higher affinity for the ER as compared with tamoxifen. Endoxifen is present in the serum at a 6- to 12-fold higher concentration as compared with 4OH-tamoxifen, and is considered to be the most important metabolite for the clinical activity of tamoxifen. Polymorphisms in CYP2D6 can increase or decrease the formation of endoxifen and may improve or diminish clinical outcomes, respectively. Although some studies have reported an association between certain CYP2D6 polymorphisms and poorer disease-free or relapse-free survival in patients receiving tamoxifen, other studies report either no relationship or the opposite effect between clinical outcomes and CYP2D6 polymorphisms. Multiple commercially available CYP2D6 assays are available, but widespread testing for patients receiving tamoxifen is not currently recommended based on available evidence.[14] Potent inhibitors of CYP2D6, such as paroxetine and fluoxetine, may decrease endoxifen levels in patients receiving tamoxifen.[14] The clinical outcomes related to such drug-drug interactions in an individual patient are largely unknown and may depend on their underlying CYP2D6 genetic status (eg, poor metabolizer, extensive metabolizer). Although high-quality evidence on strong CYP2D6 inhibitors and breast cancer outcomes in patients receiving tamoxifen is limited, many experts recommend avoidance of known strong inhibitors of CYP2D6, if possible, in patients receiving tamoxifen.

FIGURE 151-4

Tamoxifen metabolism. Widths of the arrows approximate the allocation of parent compound to various metabolites. An equation shows the metabolism of tamoxifen. The parent compound tamoxifen forms primary metabolite 4 OH-tamoxifen or 4-hydroxy tamoxifen in the presence of CYP2D6, CYP2B6, CYP2C9, CYP2C19, and CYP3A, and forms primary metabolite *N*-desmethyl tamoxifen in the presence of CYP3A45 or CYP2C9 and other CYP isoforms. Secondary metabolite endoxifen or 4-hydroxy-N-desmethyl tamoxifen is formed from 4 OH-tamoxifen in the presence of CYP3A4 5 and from N-desmethyl tamoxifen in the presence of CYP2D6. SULT1A1 and UGTs inactivate 4 OH-tamoxifen and endoxifen.

The duration of tamoxifen therapy in the adjuvant setting is 5 to 10 years. Results of several studies suggest that a longer duration (eg, 10 years vs 5 years) of tamoxifen may be more effective in some patients. Some studies showed improved disease-free survival (ATLAS trial, aTTOm trial) and improved overall survival (ATLAS trial) whereas other trials showed detrimental effects.[14,46] Increased adverse drug reactions occur with 10 years of tamoxifen therapy, including an increased risk of developing endometrial cancer (ATLAS and aTTom trials) and pulmonary embolism (ATLAS trial only) compared with those receiving tamoxifen for 5 years.[14] Based on these data, the administration of tamoxifen for 10 years can be considered in women with a higher risk of breast cancer recurrence.

The most reliable information regarding the adverse drug reactions of tamoxifen comes from the NSABP Breast Cancer Prevention Trial (P-1).[4] This trial randomized women 35 years of age or older who were at increased risk for breast cancer to placebo or to 20 mg/day of tamoxifen for 5 years. Although the primary finding of this study is that tamoxifen reduces the risk of invasive breast cancer by 49%, this study also provides comprehensive data on the risk of adverse drug reactions associated with tamoxifen. The only symptomatic differences noted between the placebo and tamoxifen group were related to hot flashes and vaginal discharge, both of which occurred more often in the tamoxifen group. No important differences between the two groups were observed in the various self-reported instruments (eg, depression scale, a global quality-of-life, and a sexual function scale). Tamoxifen did not increase the risk of ischemic heart disease but did reduce the risk of hip radius and spine fractures. The risks of stroke, pulmonary embolism, and deep vein thrombosis were higher in the tamoxifen group, particularly in women aged 50 years or older. The rate of endometrial cancer was also increased in the tamoxifen group, and this increased risk occurred primarily in women aged 50 years or older. The increased risk of endometrial carcinoma is similar in magnitude to that associated with postmenopausal estrogen replacement therapy and is likely related to an estrogenic effect of tamoxifen on the endometrium. Some experts argue that this risk is acceptable because endometrial cancer induced by tamoxifen is low stage, low grade, easily treated with surgery and does not pose a life-threatening risk to women. Tamoxifen was also associated with an increased risk of uterine sarcomas (a more aggressive form of endometrial cancer), but this risk is lower than the more common endometrial cancers identified in the study. Routine endometrial biopsy is not currently recommended for women receiving tamoxifen therapy. However, women receiving tamoxifen therapy should be counseled to have regular gynecologic examinations and immediately report unusual vaginal bleeding to their primary clinicians for further evaluation.[4]

In premenopausal women, the use of LHRH agonists (ovarian suppression) or ovarian ablation provides benefit in the adjuvant setting. Agents used to suppress ovarian function in this setting include goserelin, triptorelin, and leuprolide. A benefit was observed with goserelin as compared with CMF (cyclophosphamide, methotrexate, fluorouracil) chemotherapy in patients with hormone-sensitive premenopausal breast cancer but not in patients with hormone-receptor–negative tumors.[14] It is not clear whether the benefit of chemotherapy in this population is a result of the antitumor activity of chemotherapy or the endocrine effects of chemotherapy-induced amenorrhea. Consequently, some studies have investigated the benefits of adding ovarian ablation or suppression to chemotherapy either with or without tamoxifen. Results from these studies clearly indicate a benefit from ceasing menses regardless of whether this is caused by chemotherapy or ovarian ablation or suppression.[14] The optimal duration of adjuvant LHRH agonist use is unknown, with trials ranging from 18 months to 5 years of treatment. Two published clinical trials evaluated an LHRH agonist combined with tamoxifen or an AI in premenopausal women. In the Tamoxifen and Exemestane Trial (TEXT), premenopausal patients with hormone receptor–positive ESBC were randomized to receive 5 years of tamoxifen or exemestane, both concomitantly with triptorelin for ovarian suppression. In the Suppression of Ovarian Function Trial (SOFT), premenopausal patients with hormone receptor–positive ESBC were randomized to receive 5 years of tamoxifen alone, tamoxifen with triptorelin, or exemestane with triptorelin. Combined results of the tamoxifen/triptorelin arms and exemestane/triptorelin arms from SOFT and TEXT showed significantly prolonged 5-year disease-free survival with exemestane as compared to tamoxifen.[47] In a subsequent analysis of SOFT, the estimated 5-year disease-free survival rate was similar with tamoxifen alone versus tamoxifen with ovarian suppression.[48] As expected, patients who received tamoxifen with ovarian suppression experienced more menopausal symptoms such as hot flushes, sweating, and vaginal dryness as compared to patients who received tamoxifen alone. Based on these data, the combination of ovarian suppression and an AI is recommended in premenopausal women with hormone receptor–positive ESBC. Tamoxifen is still considered an option for adjuvant endocrine therapy in certain patients (eg, low-risk of recurrence and/or intolerance to ovarian suppression plus AI). [14]

In postmenopausal women, AIs are the standard of care in the adjuvant setting. Four different approaches to therapy have been undertaken with these agents as outlined in Table 151-7.

TABLE 151-7

Adjuvant Endocrine Therapy Options for Postmenopausal Women

Aromatase inhibitor for 5 years
Tamoxifen for 2-3 years followed by aromatase inhibitor to complete 5 years of endocrine therapy
Tamoxifen for 2-3 years followed by up to 5 years of aromatase inhibitor
Aromatase inhibitor for 2-3 years followed by tamoxifen to complete 5 years of endocrine therapy
Tamoxifen for 4.5-6 years followed by aromatase inhibitor for 5 years *or* consider tamoxifen for an additional 5 years to complete 10 years
If contraindication to aromatase inhibitors, patients who decline or are intolerant of aromatase inhibitors, tamoxifen for 5 years ≤10 years

Data from Reference 14.

Most national and international guidelines currently recommend incorporation of an AI into the adjuvant endocrine therapy regimen for all postmenopausal, hormone-sensitive breast cancers.[14] The NCCN guidelines consider the three available AIs (anastrozole, letrozole, and exemestane) to have similar antitumor efficacy and toxicity profiles. AIs are generally well tolerated. Adverse drug reactions include bone loss or osteoporosis, hot flashes, myalgias or arthralgias, vaginal dryness or atrophy, mild headaches, and diarrhea. Bone modifying agents, which are often coadministered with AIs in the metastatic setting, may also be beneficial in patients treated with AIs in the adjuvant setting (see Chapter 112, "Osteoporosis" for more detail). Other worrisome adverse drug reactions include questionable effects on the cardiovascular system (eg, hypercholesterolemia), cognitive functioning, and joint health.

All patients with ER/PR-positive breast cancer should be offered adjuvant endocrine therapy determined by their menopausal status and risk of recurrence.

Metastatic Breast Cancer (MBC, Stage IV)

Treatment of MBC with cytotoxic, endocrine, or targeted therapy often results in regression of disease and improvements in quality of life. More recent advances have also improved overall survival with the addition of biologic or targeted therapies. The choice of therapy for metastatic disease is based on the presence or absence of certain tumor characteristics. The most important predictive factors are *HER2*, estrogen, and progesterone receptors in the primary or metastatic tumor tissue. Tumors overexpressing *HER2* receptor protein are more likely to benefit from *HER2*-targeted therapy. Regimens that combine *HER2*-targeted therapy with chemotherapy are preferred first-line therapy for these patients.[49] Tumors expressing high levels of ER, PR, or both are more likely to respond to endocrine therapy. The addition of targeted therapies that overcome endocrine resistance are first-line regimens in this patient population. For TNBC, tumors expressing programmed death-ligand (PD-L1) benefit from the addition of immunotherapy to cytotoxic chemotherapy. For cases where hormone receptors and *HER2* receptors are over-expressed, an endocrine agent combined with a *HER2*-targeted agent may be considered in patients who cannot tolerate cytotoxic chemotherapy.[49] Patients with symptomatic visceral or central nervous system involvement generally have more rapidly growing cancers that require initial chemotherapy regardless of tumor marker status (eg, ER/PR).

Patients who respond to first-line therapy often respond to a second- (or even third-) line of therapy. The response rate, however, is lower and the duration of response is shorter with second- (and third-) line therapy. Patients with hormone receptor-positive MBC typically receive several sequential endocrine therapy regimens (alone or with a targeted agent) until their tumors cease to respond or the patient ceases to benefit from endocrine therapy, at which time cytotoxic chemotherapy can be administered. Subsequent chemotherapy after endocrine/targeted therapy combinations is recommended for patients who can tolerate chemotherapy. Concurrent administration of more than one endocrine therapy or combining chemotherapy plus endocrine therapy is generally avoided in the setting of MBC because of increased toxicity and no substantial improvement in overall survival. Women with hormone receptor–negative tumors; or those with rapidly progressive or symptomatic lung, liver, or bone marrow involvement (a visceral crisis); or progressive disease while on initial endocrine therapy (with or without a targeted agent) are treated with cytotoxic chemotherapy.[14] If a patient's disease progresses while on the first-line chemotherapy regimen or if the patient is unable to tolerate the regimen due to toxicities, a subsequent regimen is selected.

All breast cancer patients with bone metastases should be considered for treatment with a bone-modifying agent (eg, pamidronate, zoledronic acid, or denosumab) because these agents decrease the risk of skeletal-related events, such as fractures, spinal cord compression, and pain, and the need for radiation to the bones or surgery.[50] These agents do not act as anticancer agents and should be co-administered with other therapies targeting the cancer cells. The frequency of administration is dependent on the agent selected and could be every month versus every 3 months. See Chapter 150, "Supportive Care in Cancer" for more information

Desired Outcomes

④ MBC is currently incurable and palliation is the goal of treatment. However, some patients live for many years with metastatic disease, making this a chronic disease requiring long-term management strategies that improve or maintain quality of life. Therefore, sequential single-agent chemotherapy is often chosen over combination chemotherapy regimens, but specific clinical situations may require more rapid responses in which combination chemotherapy may be indicated. Endocrine therapy is generally better tolerated than chemotherapy and may be a more appropriate option for patients with hormone receptor–positive breast cancer. Tumor response to a particular treatment regimen may be measured by changes in laboratory tests, diagnostic imaging, and physical signs and symptoms. The patient usually continues treatment with the regimen, unless the patient cannot tolerate the regimen or the cancer is progressing at a rate that will cause symptoms (or is causing symptoms already). Optimizing quality of life is an important therapeutic end point in the treatment of patients with MBC and eventually requires discontinuation of active cancer therapy and a shift to supportive care with hospice services. Oncology clinicians, in close collaboration with their patients, consider these tradeoffs between quantity and quality of life when making treatment decisions.

Chemotherapy

⑧ Cytotoxic chemotherapy is eventually required in most patients with MBC. Most patients with MBC have tumors that lack *HER2*-overexpression. Hormone receptor–positive tumors that fail to respond to initial endocrine/targeted therapy regimens or become refractory to endocrine therapy require chemotherapy. Patients with TNBC require chemotherapy as initial therapy of metastases.

Combination chemotherapy results in an objective response in about 47% to 55% of unselected, chemotherapy-naive patients.[14] The clinical use of biomarkers and genetic panels to assist treatment decisions is relatively new. In the absence of predictive biomarkers, chemotherapy is chosen based on overall efficacy, the risk of toxicity, performance status and presence of comorbidities in the patient, aggressiveness of disease (eg, indolent vs visceral crisis), and patient preferences related to schedules, dosing route (eg, oral vs intravenous), and frequency (eg, weekly vs every 3 weeks) of the chemotherapy.

While response rates are high with combination chemotherapy, sequential use of single-agent therapies is also an effective strategy that may be preferred due to decreased rates of adverse drug reactions. In the palliative setting, when efficacy is similar, the least toxic approach is preferred. In clinical practice, patients who require a rapid response (eg, those with symptomatic bulky metastases or a visceral crisis) should receive combination chemotherapy despite the added toxicity. This decision is complex and should be made on an individual patient basis.

Most patients experience partial responses to chemotherapy. The median duration of response is highly variable, ranging from 3 to 15 months. Some patients with small volume metastatic disease will have an excellent response to an initial course of chemotherapy and may live 5 to 10 years or longer without evidence of disease. The median overall survival for patients after commonly used chemotherapy combinations ranges between 10 and 33 months. After a chemotherapy regimen has been initiated, it is usually continued until progressive disease or intolerable adverse drug reactions occur.[51] Table 151-8 lists some selected chemotherapy agents used in the metastatic setting.

TABLE 151-8

Selected Regimens for *HER2*-Negative Metastatic Breast Cancer

Single Agent Chemotherapy	

Paclitaxel[a]	**Vinorelbine**[a]
Paclitaxel 175 mg/m^2 IV Repeat cycle every 21 days *or* Paclitaxel 80 mg/m^2/week IV Repeat dose every 7 days	Vinorelbine 25 mg/m^2/week IV Repeat dose every 7 days
Capecitabine[a]	**Gemcitabine**[a]
Capecitabine 1,000-1,250 mg/m^2 orally twice daily for 14 days Repeat cycle every 21 days	Gemcitabine 800-1,200 mg/m^2/week IV, days 1, 8, and 15 Repeat cycle every 28 days
Eribulin[a]	**Liposomal Doxorubicin**[a]
Eribulin 1.4 mg/m^2 IV, days 1 and 8 Repeat cycle every 21 days	Liposomal doxorubicin 50 mg/m^2 IV Repeat cycle every 28 days
Combination Chemotherapy Regimens	
Gemcitabine + Carboplatin	**Docetaxel + Capecitabine**
Gemcitabine 1,000 mg/m^2 IV, days 1 and 8 Carboplatin AUC 2 IV, days 1 and 8 Repeat cycle every 21 days	Docetaxel 75 mg/m^2 IV, day 1 Capecitabine 950 mg/m^2 orally twice daily for 14 days Repeat cycle every 21 days
Additional Targeted Therapies	
Olaparib[a]	**Talazoparib**[a]
Olaparib tablet 300 mg orally twice daily Repeat cycle every 28 days	Talazoparib tablet 1 mg orally daily Repeat cycles every 28 days
Atezolizumab + albumin bound paclitaxel[a]	**Pembrolizumab + chemotherapy (albumin-bound paclitaxel, paclitaxel, or gemcitabine + carboplatin)**[a]
Atezolizumab 840 mg IV, days 1 and 15 Albumin-bound paclitaxel 100 mg/m^2 IV, days 1, 8, and 15 Repeat cycle every 28 days	Pembrolizumab 200 mg IV, day 1 (given every 21 days) Albumin-bound paclitaxel 100 mg/m^2 IV, days 1, 8, and 15 (given every 28 days) *OR* Paclitaxel 90 mg/m^2 IV, days 1, 8, and 15 (given every 28 days) *OR* Pembrolizumab 200 mg IV, day 1 Gemcitabine 1000 mg/m^2 IV, days 1 and 8 Carboplatin AUC 2 IV, days 1 and 8 Repeat cycle every 21 days

[a]Designated as a preferred regimen in the NCCN Breast Cancer Guidelines.

Adapted from NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines®). Breast Cancer V.3.2019. National Comprehensive Cancer Network, Inc. Accessed September 20, 2019.

Factors associated with an increased likelihood of response to chemotherapy include good performance status, a limited number (one to two) of disease sites (or involved organ systems), and prolonged previous response to chemotherapy or hormonal therapy (ie, long disease-free interval). Patients who develop progressive disease during chemotherapy have a lower likelihood of response to subsequent chemotherapy. However, this is not necessarily true for patients who are given chemotherapy after a treatment-free interval of substantial duration (eg, more than 1 year). Contrast to this, TNBC is an aggressive phenotype and is associated with poor prognosis because duration of response to chemotherapy is often short.

Many chemotherapeutic agents have demonstrated activity in the treatment of breast cancer, including doxorubicin (conventional and liposomal), epirubicin, paclitaxel (conventional and albumin-bound), docetaxel, capecitabine, fluorouracil, cyclophosphamide, methotrexate, vinblastine, vinorelbine, gemcitabine, ixabepilone, eribulin, carboplatin, cisplatin, mitomycin, thiotepa, and melphalan. The most active classes of chemotherapy in MBC are the anthracyclines and the taxanes, producing response rates as high as 50% in patients who have not received prior chemotherapy for metastatic disease.[14] Doxorubicin (conventional and liposomal) and epirubicin are generally considered therapeutically equivalent when dosed appropriately. Administration of these agents is limited by their cumulative cardiotoxicity. Paclitaxel, docetaxel, and albumin-bound paclitaxel are also FDA-approved for the treatment of MBC and are generally considered therapeutically equivalent but lack complete cross-resistance. Taxane administration is limited by cumulative peripheral neuropathy. Most patients will likely receive each of these agents at some point in the course of their MBC.

Many patients with MBC have been exposed to adjuvant chemotherapy consisting of an anthracycline and a taxane. If metastases are found within 6 to 12 months of completing treatment with these agents, many clinicians will choose a treatment from a different chemotherapy class. If it has been a long time since their adjuvant therapy, then retreating with the same agents may be considered. However, given the cardiotoxicity associated with the anthracyclines, the use of these agents in the metastatic setting has been generally avoided until the availability of liposomal anthracyclines. Pegylated liposomal doxorubicin is associated with less cardiotoxicity and similar efficacy compared with conventional doxorubicin and is a viable option for women who recur more than 1 year after their adjuvant anthracycline-containing chemotherapy regimen.[51]

Weekly administration of paclitaxel and albumin-bound paclitaxel results in higher response rates, time-to-progression, and survival and a more favorable adverse drug reaction profile compared with administration every 3 weeks.[14] With weekly administration, the toxicity profile of paclitaxel changes with less myelosuppression and delayed onset of peripheral neuropathy but slightly more fluid retention and skin and nail changes. Although the risk of hypersensitivity reactions is also slightly less at these lower doses (requiring fewer premedications), it remains at about 3% despite the incorporation of all available preventive measures. The most appropriate weekly dose of albumin-bound paclitaxel in the metastatic setting is not clear. Doses of 100 to 150 mg/m^2/week administered on days 1, 8, and 15 of a 28-day cycle have been investigated, demonstrating some evidence of a dose-response relationship. In the metastatic palliative setting, a lower dose is generally given to minimize toxicity while not significantly compromising efficacy. Docetaxel is most appropriately dosed on an every 3-week schedule for MBC. Weekly dosing did not produce improvements in disease response and was associated with significantly more toxicities than the every 3-week dosing strategy.

After patients have been treated with an anthracycline and a taxane, single-agent capecitabine, vinorelbine, or gemcitabine have resulted in response rates of 20% to 30%.[14] Of these agents, only capecitabine is FDA approved as a single agent for MBC. Gemcitabine is only FDA-approved in combination with paclitaxel for MBC. However, all of these are included in most national and international guidelines as appropriate therapy for MBC. Decisions regarding which agent to choose are based on patient characteristics, expected toxicities, and previous exposure to chemotherapy.

Other antimicrotubule agents have also been approved for the management of MBC, demonstrating significant benefits in patients who have had prior exposure to other chemotherapy agents. Ixabepilone is an epothilone with a similar but distinct mechanism of action from the taxanes, binding to β-microtubulin in a unique manner but ultimately leading to microtubule stabilization and cell death, similar to the taxanes. It is approved for use in combination with capecitabine and as a single agent. Eribulin is another antimicrotubule agent with a unique mechanism of action. The first synthetic analogue of halochondrin B, eribulin inhibits polymerization of tubulin into microtubules and suppresses the microtubule growth phase, similar to the vinca alkaloids. The mechanism of action for eribulin differs from the vinca alkaloids, in that eribulin does not appear to have any effect on the microtubule shortening phase. These subtle differences may be important for eribulin's efficacy in patients who have been exposed to multiple therapies, including other antimicrotubule agents. It is approved for use as a single agent who have received at least two prior chemotherapies for their MBC.[14] Both of these agents are associated with similar toxicities compared with the taxanes and vinca alkaloids, respectively (eg, myelosuppression, neuropathy, myalgias or arthralgias, alopecia, and skin and nail changes with ixabepilone and myelosuppression and neuropathy with eribulin). Hypersensitivity is occasionally seen with ixabepilone because it is also solubilized in Cremophor-EL, the likely causative agent in paclitaxel-associated hypersensitivity. However, eribulin has not been associated with hypersensitivity reactions and is not formulated in a complex solvent system that may predispose patients to allergic-type reactions. Neuropathy may become problematic in patients who have received numerous sequential neurotoxic chemotherapy agents.

Sacituzumab govitecan-hziy, an antibody-drug conjugate (ADC), is approved for adult patients with metastatic TNBC who received at least two prior therapies for metastatic disease. This ADC is combined with a topoisomerase I inhibitor (SN-38) that allows the antibody to target trophoblast cell surface antigen, or Trop-2, expressing cancer cells and then release the topoisomerase I inhibitor. The most common adverse drug reactions are nausea, diarrhea, and myelosuppression.[52]

Endocrine Therapy

⑨ Endocrine therapy should be considered in combination with a targeted agent as first-line therapy for patients with hormone-positive MBC, when feasible. The choice of endocrine therapy is based on the menopausal status of the patient, prior therapies and previous response, duration of response, or disease-free interval. Combinations of targeted therapies with endocrine agents may not be appropriate for all patients, and individual decisions should consider other comorbidities, the complexity of the regimen, expected adverse drug reactions, and drug or disease interactions.

The pharmacologic goal of endocrine therapy for breast cancer is to either (a) decrease circulating levels of estrogen or (b) prevent the effects of estrogen on breast cancer cells by blocking the hormone receptors or downregulating the presence of these receptors. The first goal depends on the menopausal status of the patient while the second goal is independent of menopausal status. Combinations of endocrine therapy with different mechanism of action have not demonstrated benefits over single-agent endocrine therapy and are generally not recommended outside the context of a clinical trial.

Several different classes of targeted agents are now approved in combination with endocrine therapy. These combinations address de novo or acquired resistance with endocrine therapy alone and have demonstrated efficacy over single agents in specific patient populations. However, combination therapy is generally associated with increased toxicity compared with single agent endocrine therapy. Optimal subsequent therapy after progression on initial targeted-endocrine treatment is largely unknown and the subject of ongoing clinical trials. However, most patients with hormone-positive MBC will receive several lines of targeted-endocrine combination regimens or endocrine therapy alone sequentially before chemotherapy is considered.

Outside of regimens that include novel targeted agents, little evidence exists that the survival benefit from one endocrine therapy is clearly superior to that achieved with other therapies in women with MBC. Prior to the availability of targeted agents, randomized controlled trials comparing different endocrine therapies (eg, antiestrogens, AIs, progestins, estrogens, androgens) and surgical procedures (eg, oophorectomy, adrenalectomy, and hypophysectomy) showed similar overall survival in patients with MBC. Therefore, the choice of a particular endocrine therapy was based primarily on the mechanism of action, toxicity, and patient preference (see Tables 151-9 and 151-10). Based on these criteria, AIs, tamoxifen or toremifene, and fulvestrant are the preferred initial agents in MBC except when the patient's cancer recurs during or within one year of adjuvant therapy with the same class of agent. In these cases, therapies from a different pharmacologic class were indicated.

TABLE 151-9

Drug Monitoring for Endocrine Therapies

Drug	Adverse Drug Reaction	Monitoring Parameters	Comments
Aromatase inhibitors	• Hot flashes • Arthralgias or myalgias • Osteoporosis • Hypercholesterolemia	• Patient assessment • BMD • Lipid panel	• Interval of monitoring controversial
Antiestrogens: SERMs[a]	• Hot flashes • Endometrial hyperplasia or cancer • Venous thromboembolism • Osteopenia (premenopausal women only)	• Patient assessment • Annual gynecologic assessment • Consider BMD for premenopausal women	• Routine transvaginal ultrasonography and endometrial biopsies are not recommended in the absence of symptoms
Antiestrogens: SERDs[a]	• Hot flashes • Injection-site reactions	• Patient assessment	
LHRH agonists	• Hot flashes • Injection-site reactions • Osteoporosis	• Patient assessment • BMD	

BMD, bone mineral density.

[a] Liver function tests obtained periodically to screen for changes in hepatic elimination, hepatotoxicity and the presence of hepatic metastases.

TABLE 151-10

Therapies Used for Hormone Receptor–Positive Metastatic Breast Cancer

Drug	Initial Dose	Special Population Dose	Comments
Aromatase Inhibitors: Nonsteroidal			
Anastrozole	1 mg orally daily		
Letrozole	2.5 mg orally daily	Caution in severe liver impairment[a]	
Aromatase Inhibitor: Steroidal			
Exemestane	25 mg orally daily		Take after meals
Antiestrogens: SERMs			

Tamoxifen	20 mg orally daily	See text regarding *CYP2D6*	
Toremifene	60 mg orally daily		
Antiestrogen: SERD			
Fulvestrant	500 mg IM every 28 days (after loading days 1, 15, 29)	Moderate liver impairment[a] administer 250 mg IM every 28 days (after loading days 1, 15, 29)	
LHRH Agonists			
Goserelin	3.6 mg SC every 28 days	Premenopausal women only	
Leuprolide	3.75 mg IM every 28 days	Premenopausal women only	Not FDA approved for breast cancer; other formulations are administered differently
Triptorelin	3.75 mg IM every 28 days	Premenopausal women only	Not FDA-approved for breast cancer
Biologic/Targeted Therapies			
Abemaciclib (+/− Letrozole or Fulvestrant)	Single agent 200 mg orally twice a day continuously **OR** Combination 150 mg orally twice a day continuously	Adjust dose for diarrhea, myelosuppression, and/or severe hepatic impairment. Monitor for hepatotoxicity and thromboembolism. Avoid concomitant strong inhibitors of *CYP3A4* and moderate/strong inducers of *CYP3A4*	Do not split tablets
Palbociclib (+ Letrozole or Fulvestrant)	125 mg orally daily × 21 days, followed by 7 days off, repeated every 28 days	Adjust dose for myelosuppression and severe hepatic impairment. Monitor for nausea, diarrhea, and hepatotoxicity. Avoid concomitant strong inhibitors of *CYP3A4* and moderate/strong inducers of *CYP3A4*	● Do not split tablets ● Take with meals (capsules only)
Ribociclib (+ Letrozole or Fulvestrant)	600 mg orally daily × 21 days, followed by 7 days off, repeated every 28 days	Adjust dose for myelosuppression and/or severe hepatic or renal impairment. Monitor for hepatotoxicity and QT prolongation. Avoid concomitant strong inhibitors of *CYP3A4* and moderate/strong inducers of *CYP3A4*	Do not split tablets
Alpelisib (+ Fulvestrant)	300 mg orally daily	Adjust dose for dermatologic toxicity, hyperglycemia and diarrhea. Monitor for hyperglycemia and dermatologic toxicity. Avoid concomitant strong inducers of *CYP3A4*	Take after meals. Do not split tablets
Everolimus (+ Exemestane or Fulvestrant or Tamoxifen)	10 mg orally daily	Adjust dose in mild, moderate and severe liver impairment; also monitor for myelosuppression, hyperglycemia, dyslipidemia, renal dysfunction. May need to adjust dose with concomitant CYP3A4 inhibitors/inducers	Do not split tablets

IM, intramuscular; SC, subcutaneous.

[a]Severe liver impairment: Child-Pugh class C; moderate liver impairment: Child-Pugh class B; minor liver impairment: Child-Pugh class A.

In postmenopausal women, the main source of estrogen is derived from the peripheral conversion of androstenedione produced by the adrenal gland into estrone and estradiol. This conversion requires the enzyme aromatase. Aromatase also catalyzes the conversion of androgens to estrogens in the ovary in premenopausal women and in extraglandular tissues (eg, the breast and breast cancer cells) in postmenopausal women. Therefore, AIs effectively reduce the levels of estrogens in circulation and in the target organ. Third-generation AIs include anastrozole, letrozole, and exemestane. A major advantage of these specific compounds is their toxicity profile, which consists mainly of bone loss and osteoporosis, mild nausea, hot flashes, arthralgias/myalgias, and mild fatigue. Anastrozole and letrozole are nonsteroidal triazole compounds that reversibly and competitively inhibit aromatase; they have no intrinsic hormonal activity. Exemestane is a steroidal compound that binds irreversibly to aromatase, forming a covalent bond. Although this mechanism may have theoretical advantages to the reversible binding of the nonsteroidal agents, no clinical evidence that this drug is superior to other agents in this class exists. AIs should only be used in postmenopausal women. Pre- or perimenopausal women, whose ovaries are functioning, are not appropriate candidates for these therapies, but the use of AIs in addition to ovarian ablation or suppression (eg, oophorectomy or LHRH agonists) is appropriate and acceptable.

Antiestrogens bind to ERs, which inhibit receptor-mediated gene transcription and therefore block the effect of estrogen on the end target. This class of agents is subdivided into two pharmacologic categories, SERMs and selective estrogen receptor downregulators (SERDs). SERMs include tamoxifen and toremifene (and raloxifene for breast cancer–risk reduction in high-risk women) and demonstrate tissue-specific activity, both estrogenic and antiestrogenic, as described previously. The agonist activity is thought to be responsible for many of the adverse reactions seen with these agents, including the increased risk of endometrial cancer, and has led to the development of pure ER antagonists that lack estrogen agonist activity. SERDs are also referred to as pure antiestrogens. These molecules bind to ER, inhibit estrogen binding, and degrade the drug–ER complex, thus decreasing the amount of ER expressed. Fulvestrant is currently the only pure antiestrogen currently commercially available in the United States.

The most commonly utilized SERM in the treatment of breast cancer is tamoxifen. The toxicities of tamoxifen are described in the “Endocrine Therapy” section under Curative Breast Cancer. The only additional toxicity that may be observed in the setting of MBC (specifically bone metastases) is a tumor flare or hypercalcemia, which occurs in about 5% of patients after the initiation of any SERM therapy and is not an indication to discontinue the drug. It is generally accepted that this reaction is associated with response to endocrine therapy, but patients who do not experience such a reaction may still respond. This reaction is seen less frequently with the concurrent use of bisphosphonates as a result of their inhibition of osteoclasts, subsequently preventing the release of calcium from the bone.

Toremifene is another commercially available SERM for the treatment of breast cancer. It exhibits similar efficacy and tolerability compared with tamoxifen in the metastatic setting. Cross-resistance to toremifene has been demonstrated in patients with tamoxifen-refractory disease. Details regarding its metabolism are available and indicate it may be an alternative to tamoxifen in settings where there are concerns regarding drug interactions. However, toremifene use in the United States is minimal.[53] Raloxifene, another SERM, was originally approved for the prevention of osteoporosis in postmenopausal women. Available data with raloxifene as a treatment for breast cancer show low response rates and no significant clinical benefit. Consequently, the use of this agent for breast cancer treatment should be discouraged. The clinical benefits of raloxifene for breast cancer risk reduction in high-risk postmenopausal women have been discussed (see the “Prevention and Early Detection” section).

Fulvestrant, an SERD, is approved for the second-line therapy of postmenopausal patients with hormone receptor–positive tumors either alone or in combination with targeted therapy. When combined with ovarian suppression or ablation, fulvestrant is an appropriate therapy in premenopausal women. It is unique, in that it is given as an intramuscular injection. Adverse drug reactions related to fulvestrant include injection-site reactions, hot flashes, asthenia, and headaches.

In premenopausal women, one of the goals of endocrine therapy is to reduce estrogen production which can be accomplished with surgery, radiation, or medication. While radiotherapeutic ablation of the ovaries is effective, this approach is typically not used in the United States because of its morbidity. Medical ovarian suppression with LHRH analogs is increasingly used instead of oophorectomy in premenopausal women. Because the effects of the LHRH analogs are reversible, the administration of these agents may also determine how a patient will tolerate estrogen deprivation. If the patient tolerates this therapy, then an oophorectomy may be recommended as a permanent therapeutic intervention.

The activity of LHRH analogs is related to its ability to downregulate LHRH receptors in the pituitary and decrease luteinizing hormone levels, which subsequently decreases circulating estrogen to suppressed/ablated levels. Therefore, the effect of LHRH analogs on circulating estrogen levels in premenopausal breast cancer is similar to an oophorectomy. The three agents available in the United States are leuprolide, goserelin, and triptorelin, but only goserelin is FDA-approved for the treatment of MBC. These agents are administered as an injection every 4 weeks (all products have extended formulations, lasting 3 months to 1 year, but they are not recommended for the initial treatment of breast cancer) and are associated with minimal adverse drug reactions, including amenorrhea, bone loss or osteoporosis, hot flashes, and occasional nausea (see Table 151-9). LHRH analogs may also produce a flare response because of an initial surge in luteinizing hormone and estrogen production lasting 2 to 4 weeks. This flare response is similar to that seen with tamoxifen, and patients with high-volume, bulky disease should be monitored for increasing pain and hypercalcemia during the initiation period.

Biologic or Targeted Therapy

⑩ Therapies directed at molecular targets through novel mechanisms are often referred to as targeted therapy. Many of the targeted therapies are also biologic therapies because they are mAbs. For breast cancer, several agents are directed at targets that are differentially expressed in breast cancer cells and play a critical role in their proliferation and survival.

CDK Inhibitors

CDK, in coordination with their regulatory cyclin partners, form CDK-cyclin heterodimer complexes that control cell cycling. CDK-4 and -6 are critical components of this process. In some breast cancer cell lines, these complexes are responsible for phosphorylating the retinoblastoma tumor suppressor gene product, or RB, thus inactivating the suppression of cell division and allowing unregulated progression through the cell cycle. Three CDK-inhibitors have an FDA-approved indication for MBC (abemaciclib, palbociclib, and ribociclib). These agents selectively inhibit CDK-4 and -6, effectively preventing retinoblastoma tumor suppressor gene product phosphorylation and leaving it in an active state that is able to appropriately regulate cell division. CDK inhibitors have improved progression-free survival in combination with AIs (as first-line therapy) and fulvestrant (as first- and second-line therapy) (see Table 151-10). A CDK inhibitor-containing regimen should be considered as first-line therapy in newly diagnosed patients with *HER2*-negative, hormone receptor–positive MBC. The addition of the CDK inhibitor to endocrine therapy increases the toxicity of the regimen. Neutropenia (all grades) is the dose-limiting toxicity of palbociclib and ribociclib and is also fairly common with abemaciclib. However, low rates of neutropenic fever and other infections have been reported. The dose-limiting adverse drug reaction with abemaciclib is diarrhea and occurs in nearly all patients. Diarrhea is typically managed with dose reductions and medical interventions, allowing most patients to continue therapy. Ribociclib also has a warning in its labeling for QT prolongation and requires electrocardiogram monitoring for the first two cycles.[54]

Mammalian Target of Rapamycin (mTOR) Inhibitors

The phosphatidylinositol 3-kinase (PI3K)/protein kinase-B (also called Akt) pathway includes many different proteins, of which one of the most important is the mTOR tyrosine kinase. mTOR is an important mediator for cell proliferation and regulation of apoptosis, angiogenesis, and cellular metabolism. Everolimus, an oral mTOR inhibitor, improved progression-free survival when given in combination with either exemestane, fulvestrant, or tamoxifen and should be considered in patients with hormone receptor–positive MBC whose disease has progressed within a year of or while receiving endocrine therapy (see Table 151-10). The choice of endocrine therapy depends on what endocrine therapy the patient received previously.

The most common serious (grade 3 or 4) adverse drug reactions reported in the combination everolimus/exemestane trial were stomatitis, anemia, dyspnea, and pneumonitis. Adverse metabolic effects can be seen and monitoring should include fasting glucose, hemoglobin A1C, and lipid panel.

PI3K Inhibitors

PI3Ks play a critical role in regulating many biological functions including cell growth, proliferation, and survival.[55] Alpelisib, a PI3K inhibitor, is approved in combination with fulvestrant for postmenopausal women and men, with hormone receptor–positive, *HER2*-negative, PIK3CA-mutated, advanced or metastatic breast cancer as detected by an FDA-approved test following progression on or after an endocrine-based regimen.

Several important toxicities associated with alpelisib require close monitoring and may lead to dose reductions due to intolerability. Hyperglycemia, including ketoacidosis, may occur with alpelisib and patients’ fasting glucose should be monitored closely especially upon initiation of this agent. Many patients will require medical intervention with antidiabetic medications. Other adverse drug reactions that may be significant include rash and diarrhea. Antihistamine administration prior to rash onset may decrease rash incidence/severity and should be considering upon initiation of alpelisib.

Poly (ADP-Ribose) Polymerase (PARP) Inhibitors

PARP is a family of enzymes partially responsible for repairing single-strand DNA breaks. Patients who harbor a germline mutation in *BRCA1* or *BRCA2* have impaired ability to repair double-strand DNA breaks. TNBC is strongly associated with germline mutations in the *BRCA1* gene.[56] These patients are candidates for therapy with the PARP inhibitors. Olaparib and talazoparib, given as single agents, improve progression-free survival compared with single-agent chemotherapy in patients with *HER2*-negative MBC who had a germline mutation in *BRCA1* or *BRCA2*. Rates of severe adverse drug reactions (grade 3 or higher) are less common with the PARP inhibitors compared with chemotherapy. Commonly reported adverse drug reactions of PARP inhibitors include anemia, nausea, vomiting, diarrhea, and fatigue.[57]

HER2-Targeted Agents

HER2 is an important protein for maintenance of breast cancer cell proliferation and survival. The *HER2*-targeted agents currently available in the United States are trastuzumab, pertuzumab, ado-trastuzumab emtansine, fam-trastuzumab deruxtecan, margetuximab, lapatinib, neratinib, and tucatinib. To date, no benefit has been observed with the administration of trastuzumab to patients with *HER2*-negative tumors (IHC score of 0-1+, or FISH negative) and a questionable benefit has been observed with administration of trastuzumab to women with tumors that are 2+ for *HER2* by IHC staining alone. As mentioned previously, trastuzumab is a mAb targeted against the *HER2*-receptor protein. Pertuzumab is also a mAb but binds to a different epitope on *HER2* and prevents protein dimerization and subsequent cell signaling. Ado-trastuzumab emtansine and fam-trastuzumab deruxtecan are ADC with a trastuzumab backbone linked to cytotoxic chemotherapy. In the case of ado-trastuzumab, the chemotherapy portion is a potent tubulin inhibitor and in fam-trastuzumab deruxtecan, a topoisomerase inhibitor. Lapatinib, neratinib, and tucatinib are small-molecule tyrosine kinase inhibitors targeted against the *HER2* protein, leading to cell signaling blockade and decreased cell proliferation.

First-line therapy with a pertuzumab-trastuzumab-taxane combination is the preferred option for *HER2*-overexpressing MBC in patients who have not received pertuzumab in the neoadjuvant or adjuvant setting. Docetaxel administered every 3 weeks in combination with trastuzumab and pertuzumab (both administered every 3 weeks) has the most evidence to support its use in this setting. Substitution of docetaxel with weekly paclitaxel may be used if patients cannot tolerate docetaxel.[58]

Ado-trastuzumab emtansine is the recommended second-line *HER2*-targeted therapy for MBC after a patient progresses on or can no longer tolerate first-line therapy. Subsequent therapy (third-line) for *HER2*-positive MBC is controversial. Choice of regimen may depend on the presence of brain metastases, organ function, and residual toxicities from previous regimens. Possible options include fam-trastuzumab deruxtecan, tucatinib + trastuzumab + capecitabine, a lapatinib combination regimen, a chemotherapy + trastuzumab combination, margetuximab-cmkb + chemotherapy, or neratinib + capecitabine. For patients with tumors that are hormone receptor-positive, endocrine therapy, either alone or with trastuzumab or lapatinib, is an option.

Brain metastases are common in patients with *HER2*-positive MBC, with over 50% of patients experiencing brain metastases over their lifetime. This statistic is somewhat misleading because the brain is an uncommon site of first recurrence in patients with ESBC (1%-3%); this observation is related to the overall success of *HER2*-targeted therapy at extracranial sites and the ability of the blood-brain barrier to prevent *HER2*-targeted mAb from accessing these tissues, creating a sanctuary site for breast cancer cells. Nonetheless, responses in the brain have been reported with the large, *HER2*-targeted antibodies and are likely due to disruptions in the blood-brain barrier from disease or prior local therapy (surgery or radiation). The small molecule tyrosine kinase inhibitors, particularly tucatinib, have shown efficacy in patients with brain metastases, but local therapies tend to offer the best approach in combination with systemic therapy. Local therapy including surgery, whole-brain radiation, stereotactic radiosurgery, or some combination of these approaches is considered as initial therapy. Systemic therapy is continued if the other metastatic sites are stable. If extracranial metastases are progressing, a change in the *HER2*-targeted therapy according to guidelines is appropriate. If local therapy fails to control disease in the brain, best supportive or palliative care may be indicated, depending on the status of their extracranial sites of disease and their overall performance status.[59]

Adverse drug reactions of *HER2*-targeted therapies are primarily related to the heart. All therapies in this class, regardless of their exact mechanism of receptor blockade, have some degree of cardiotoxicity. Heart failure associated with trastuzumab is somewhat reversible with pharmacologic management, and some patients have continued therapy with trastuzumab after their left ventricular ejection fraction has returned to normal with medical management and/or a pause in therapy. Close monitoring for clinical signs and symptoms of heart failure and routine echocardiography are recommended in order to intervene with appropriate cardiac treatments for all patients on *HER2*-targeted agents. Rare QT prolongation has also been reported with lapatinib, but the clinical significance of this effect is unclear. Concurrent administration of drugs that increase systemic exposure to lapatinib or have similar effects on QT interval may predispose patients to this rare complication and warrant closer monitoring.

Infusion-related reactions (primarily fever and chills) are associated with mAbs and are seen with trastuzumab, pertuzumab, ado-trastuzumab emtansine, fam-trastuzumab deruxtecan, and margetuximab. These reactions can range depending on the agent but may occur in up to 40% of patients receiving trastuzumab.[39] Postmarketing surveillance data have identified pulmonary toxicity and anaphylaxis as rare but potentially life-threatening reactions associated with trastuzumab. Other infusion-related reactions may include mild nausea, pain at tumor sites, rigors, headaches, dizziness, hypotension, rash, and asthenia, which are much less common. If patients experience mild hypersensitivity reactions, they may require the addition of premedications to mitigate this response. If the reaction is more severe, they may be unable to safely receive subsequent doses.

Several *HER2*-targeted therapies, particularly fam-trastuzumab deruxtecan, have been associated with interstitial lung disease. Drug-induced interstitial lung disease includes conditions like pulmonary fibrosis and inflammation that may be life-threatening.[60] Treatment for this toxicity may include corticosteroids and depending on severity may require patient to discontinue therapy with the agent.

Other adverse drug reactions associated with *HER2*-targeted therapies may include rash and diarrhea. Diarrhea is more significant for patients treated with pertuzumab and when *HER2* TKIs are used in combination with chemotherapy (eg, neratinib plus capecitabine). This adverse drug reaction is generally manageable with aggressive antidiarrheal therapy or dose reductions. Other rare effects have been reported (QT prolongation, hepatotoxicity) and patients should be counseled regarding these effects. Drug–drug and drug–food interactions are particularly important with the *HER2* TKIs because of their metabolism through CYP enzymes and other pharmacokinetic and pharmacodynamic issues. Many of the adverse drug reactions listed previously may be exacerbated by drug or food interactions, and careful review of patients' medication lists and education regarding these issues is extremely important.

Immunotherapy

While mAbs against programmed cell death protein 1 (PD-1) and programmed death-ligand (PD-L1) have failed to demonstrate antitumor activity as single agents in MBC, combining these agents with traditional chemotherapy have proven effective in certain patient populations. Most recently, several chemotherapy-immunotherapy combinations have been FDA approved for treatment of patients with metastatic TNBC whose tumors express PD-L1. Pembrolizumab (mAb against PD-1) is approved in combination with albumin-bound paclitaxel, paclitaxel, or the combination of carboplatin + gemcitabine. Atezolizumab (mAb against PD-L1) is approved in combination with albumin-bound paclitaxel (see Table 151-8). Adverse drug reactions reported with the addition of immune therapies to traditional chemotherapy can be substantial and require close monitoring. Immune-related toxicities may include rash, colitis, hepatitis, hyper/hypothyroidism, and pneumonitis.

Radiation Therapy

Radiation is an important modality in the treatment of symptomatic MBC. The most common indication for treatment with radiation therapy is painful bone metastases or other localized sites of disease refractory to systemic therapy. Radiation therapy provides significant pain relief to about 90% of patients who are treated for painful bone metastases. Radiation is also an important modality in the palliative treatment of metastatic brain lesions and spinal cord lesions, which respond poorly to systemic therapy, as well as eye or orbit lesions and other sites where significant accumulation of tumor cells occurs. Skin and lymph node metastases confined to the chest wall area may also be treated with radiation therapy for palliation (eg, open wounds or painful lesions). Chemotherapy may also be added to radiation for sensitization purposes in certain circumstances.

EVALUATION OF THERAPEUTIC OUTCOMES

The desired therapeutic outcome for ESBC differs significantly from that of MBC. Surgery, radiation, neoadjuvant/adjuvant therapy—chemotherapy, biologic or targeted therapy, and endocrine therapy—is conducted and administered, respectively, with curative intent. Adjuvant therapy is intended to eradicate micrometastases and thus cure the patient of breast cancer. Neoadjuvant therapy is administered to reduce the tumor size prior to surgery and/or to allow breast conserving surgery if the patient desires. In addition, neoadjuvant therapy allows assessment of response or sensitivity to chemotherapy and/or biologic/targeted therapy. In the neoadjuvant setting, local imaging, such as mammogram or ultrasound, is done to assess tumor response to chemotherapy, biologic or targeted therapy, or endocrine therapy. The overall goal of neoadjuvant and adjuvant therapy is to cure the disease, which cannot be fully evaluated for years after initial diagnosis and treatment. Patients are recommended to have a history and physical every 3 to 6 months for the first 3 years after completion of primary therapy, every 6 months for the following 2 years, and then yearly thereafter. Routine laboratory tests or imaging are not recommended unless there is suspicion of recurrence or metastatic disease.[61]

Palliation is the therapeutic outcome in the treatment of MBC. Optimizing benefits and minimizing toxicity are general therapeutic goals of any therapy administered in this setting. Careful consideration of quality of life is important in this setting. Tumor response to a particular treatment regimen may be measured by changes in laboratory tests, diagnostic imaging, or physical signs or symptoms. The patient usually continues treatment with the regimen, unless the patient cannot tolerate the regimen or the cancer is progressing at a rate that will cause symptoms (or is causing symptoms already). Optimizing quality of life is an important therapeutic end point in the treatment of patients with MBC and eventually requires discontinuation of active cancer therapy and a shift to supportive care with hospice services.

ABBREVIATIONS

ACS	American Cancer Society
ADC	antibody-drug conjugate
AI	aromatase inhibitor
ALND	axillary lymph node dissection
ASCO	American Society of Clinical Oncology
BCT	breast-conserving therapy

SELF-ASSESSMENT QUESTIONS

1. Which of the following accurately describes breast cancer?

    A. Breast cancer mortality has increased since the 1990s.

    B. Incidence of breast cancer is lower in White women compared to Black women.

    C. Most breast cancers are diagnosed at an early stage.

    D. Median age at diagnosis of breast cancer is 54 years of age.

2. CB is a 35-year-old woman with a known *BRCA1* mutation. According to the American Cancer Society, which of the following screening modalities would be recommended for CB annually?

    A. Mammogram and clinical breast examination

    B. Mammogram alone

    C. Breast MRI and mammogram

    D. Breast MRI and clinical breast examination

3. JR is a patient with newly diagnosed hormone receptor-positive, *HER2*-negative MBC. The metastatic disease is in the spine and liver and causes pain. JR has not been previously treated for MBC and needs chemotherapy. Which would be the most appropriate treatment for JR?

    A. Capecitabine

    B. Vinorelbine

    C. Gemcitabine

    D. Paclitaxel

4. Which of the following agents is appropriate regarding the treatment of patients with hormone receptor–positive DCIS?

   A. Raloxifene may be used in premenopausal patients.

   B. Raloxifene, exemestane, and anastrozole may be used in postmenopausal patients.

   C. Anastrozole may be used in premenopausal patients.

   D. Tamoxifen may be used in premenopausal and postmenopausal patients.

5. The treatment of early-stage breast cancer is complex because rapid changes in clinical trials for chemotherapy are reported. Although this is the case, what information is now well-established?

   A. Patients with lymph node metastases should not receive chemotherapy.

   B. NCCN guidelines and ASCO guidelines are not reliable to go to for treatment updates.

   C. Patients with ER/PR positive tumors do not benefit from chemotherapy.

   D. Taxanes added to anthracycline chemotherapy provide beneficial treatment.

6. When comparing BCT to a modified radical mastectomy, which of the following statements is true?

   A. BCT is associated with similar survival outcomes

   B. BCT is associated with decreased local recurrence rates

   C. A modified radical mastectomy is associated with improved survival

   D. BCT is associated with increased local recurrence rates and decreased survival

7. Which of the following adjuvant chemotherapy combinations is most appropriate for the treatment of early-stage breast cancer?

   A. Doxorubicin, cyclophosphamide (AC) followed by weekly paclitaxel

   B. Fluorouracil, leucovorin, oxaliplatin (FOLFOX)

   C. Cyclophosphamide, doxorubicin, vincristine, prednisone (CHOP)

   D. Doxorubicin, paclitaxel (AT)

8. Which of the following adjuvant endocrine therapy regimens is most appropriate for a postmenopausal woman with early-stage breast cancer?

   A. Anastrozole × 5 years

   B. Letrozole × 2 years

   C. Fulvestrant × 2 years

   D. Tamoxifen × 5 years

9. MR is a 42-year-old individual with newly diagnosed inflammatory right breast cancer. What is the best option for primary therapy?

   A. Surgery

   B. Radiation

   C. Neoadjuvant chemotherapy

D. Neoadjuvant endocrine therapy

10. Which of the following is correct regarding goal of treatment?

    A. Adjuvant anastrozole in early breast cancer is for palliation

    B. Margetuximab in MBC is for cure

    C. Sacituzumab govitecan in breast cancer is for cure

    D. Capecitabine in MBC is for palliation

11. Which of the following hormonal therapies is most appropriate for adjuvant treatment in a premenopausal individual?

    A. Anastrozole

    B. Fulvestrant

    C. Exemestane

    D. Tamoxifen

12. SW is a 66-year-old postmenopausal individual with newly diagnosed MBC to the lung (ER/PR positive; *HER2*-negative). This was found on a chest x-ray and was confirmed by CT scan and biopsy. SW is otherwise asymptomatic from the cancer and feels well. Which of the following regimens would be best to treat the cancer?

    A. Letrozole plus palbociclib

    B. Lapatinib plus capecitabine

    C. Trastuzumab

    D. Paclitaxel

13. DB is a 35-year-old premenopausal individual with a germline mutation in *BRCA1* and newly diagnosed metastatic TNBC. Adjuvant chemotherapy (anthracycline- and taxane-containing regimen) was completed for a locally advanced breast cancer approximately 7 months ago. DB now has liver metastases with normal blood work and minimal symptoms. Which of the following regimens would benefit the patient the most?

    A. Letrozole

    B. Docetaxel with trastuzumab

    C. Capecitabine

    D. Olaparib

14. Which of the following agents prevent *HER2*-protein dimerization and subsequent cell signaling?

    A. Lapatinib

    B. Pertuzumab

    C. Everolimus

    D. Trastuzumab

15. MM is a 56-year-old postmenopausal individual with newly diagnosed *HER*2-positive, hormone receptor-negative, metastatic breast cancer to the liver and lungs. This cancer was originally diagnosed 3 years prior and received neoadjuvant TCHP (docetaxel, carboplatin, trastuzumab,

pertuzumab) with excellent results. The plan for therapy is ado-trastuzumab emtansine. Which of the following adverse drug reactions should be discussed with the patient during the informed consent process?

A. Renal dysfunction

B. Seizures

C. Cardiotoxicity

D. Hypertension

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Most breast cancers are diagnosed in early stages. A is incorrect because mortality has decreased since the 1990s. B is incorrect because the incidence is higher in White individual. D is incorrect because the median age at diagnosis of breast cancer is 62 years. Refer to the "Introduction" section for further details.

2. **C.** Breast MRI and mammogram are recommended annually for this specific group of individuals by ACS. A is incorrect because ACS does not recommend clinical breast examination, B is incorrect because annual breast MRI is recommended with annual mammography, and D is incorrect because ACS does not recommend clinical breast examination and recommends both annual breast MRI is recommended with annual mammography, instead of breast MRI alone. Refer to Table 151-2 for further details.

3. **D.** This cancer has not been previously been treated, and paclitaxel is a taxane which is one of the most active classes of chemotherapy in breast cancer. A, B, and C are incorrect because these are options for patients once they have been treated with anthracyclines and taxanes. Refer to the "Chemotherapy" section under MBC (Stage IV) section for further details.

4. **D.** Tamoxifen may be used in premenopausal and postmenopausal patients. A is incorrect because raloxifene is not to be used in treatment of DCIS but rather in the prevention setting and is to be given only to postmenopausal patients. B is incorrect because raloxifene and exemestane are not to be used in treatment of DCIS but rather in the prevention setting. C is incorrect because although anastrozole may be given in the treatment of DCIS, it is only for postmenopausal patients. Refer to the "Noninvasive Carcinoma" and "Treatment" sections under Pathophysiology section and for specifics about prevention, and see the Prevention and Early Detection section for further details.

5. **D.** There is benefit when taxanes are added to anthracycline chemotherapy. A is incorrect because in patients with lymph node metastases chemotherapy is recommended in most patients. B is incorrect because NCCN guidelines and ASCO guidelines are reliable to go for treatment updates. C is incorrect because patient benefits from chemotherapy are seen regardless of ER/PR status. Refer to "Systemic Therapy" and "Cytotoxic Chemotherapy" sections under Curative Breast Cancer (Stages I-III) for further details.

6. **A.** BCT is associated with similar survival outcomes. B is incorrect because BCT is associated with a small increase in the risk of local recurrence. C is incorrect because mastectomy is associated with similar survival rates compared to BCT. D is incorrect because BCT is associated with a small increase in the risk of local recurrence and similar survival rates compared to mastectomy. Refer to the "Locoregional Therapy" section under Curative Breast Cancer (Stages I-III) for further details.

7. **A.** Doxorubicin, cyclophosphamide (AC) followed by weekly paclitaxel is the only one of the four regimens now used in breast cancer. B and C are incorrect because these are not chemotherapy regimens used in breast cancer. D is incorrect because "doxorubicin, paclitaxel (AT)" is not a chemotherapy regimen used in breast cancer. Refer to Table 151-5 for further details.

8. **A.** This is a postmenopausal individual being treated with adjuvant endocrine therapy and of the choices, anastrozole × 5 years is the most appropriate. B is incorrect because letrozole should be either for 5 years or the 2 years of treatment should be followed by tamoxifen. C is incorrect because fulvestrant is not appropriate in the adjuvant setting for breast cancer. D is incorrect because in a postmenopausal patient, tamoxifen is followed by an AI for 5 years or 5 additional years of tamoxifen. Refer to Table 151-7 for further details.

9. **C.** Since MR has inflammatory breast cancer, neoadjuvant chemotherapy is the best option for primary therapy rather than surgery (answer A) or radiation therapy (answer B). D is incorrect because this is neoadjuvant endocrine therapy and in the case, hormone receptor status is unknown.

Refer to “Systemic Therapy” and “Cytotoxic Chemotherapy” sections under Curative Breast Cancer (Stages I-III) for further details.

10. **D.** The goal of treatment in MBC is palliation. A is incorrect because adjuvant anastrozole in early breast cancer is for cure. B is incorrect because margetuximab in MBC is for palliation. C is incorrect because sacituzmab govitecan in breast cancer is only for use in the MBC setting and in that setting, the goal is palliation. Refer to “Desired Outcomes” and “Systemic Therapy; Endocrine Therapy” sections under Curative Breast Cancer (Stage I-III), “Biologic or Targeted Therapy”, “HER2-Targeted Agents”, “Chemotherapy”, and “Desired Outcomes” under MBC (Stage IV).
11. **D.** Of the listed option, tamoxifen would be the most correct due to the patient’s premenopausal status. A, B, and C are incorrect because these are all to be given to only postmenopausal and not to premenopausal patients. Refer to “Endocrine Therapy” section under Curative Breast Cancer (Stage I-III).
12. **A.** For an asymptomatic patient with HR-positive, *HER2*-negative metastatic breast cancer, the first-line of therapy should be an endocrine-based regimen. Data with the CDK-inhibitors indicate improvements in progression-free survival with the addition of palbociclib to letrozole (and fulvestrant). B, C, and D are incorrect because these are not endocrine-based regimens. See “Biologic or Targeted Therapy” and “CDK Inhibitors” section under MBC (Stage IV) section.
13. **D.** A patient such as this with *BRCA*-mutation and TNBC would benefit from a PARP inhibitor such as olaparib in favor of single agent chemotherapy due to improved progression-free survival. A is incorrect because letrozole is endocrine therapy and this patient has TNBC. B is incorrect because trastuzumab is for patients with *HER2*-positive breast cancer and this patient is not *HER2*-positive. C is incorrect because capecitabine is single agent chemotherapy for which olaparib showed better progression-free survival. See “Biologic or Targeted Therapy” and “Poly-ADP ribose polymerase (PARP) inhibitors” section under MBC (Stage IV) section.
14. **B.** Pertuzumab is the only agent that prevents *HER2* dimerization and subsequently inhibits cell cycle signaling. A, C, and D are incorrect because this is not the mechanism of action for any of these agents. See “Biologic or Targeted Therapy” and “HER2-Targeted Agents” sections under MBC (Stage IV) section.
15. **C.** Ado-trastuzumab emtansine is a mAb against *HER2* linked to a cytotoxic drug, and thus it imparts some increased risk of cardiotoxicity associated with its use. A, B, and D are not associated with ado-trastuzumab emtansine. See “Biologic or Targeted Therapy” and “HER2-Targeted Agents” sections under MBC (Stage IV) and “Biologic or Targeted Therapy” section under Curative Breast Cancer (Stage I-III).

Chapter 152: Lung Cancer

Keith A. Hecht; Eve M. Segal

KEY CONCEPTS

KEY CONCEPTS

① Lung cancer is the leading cause of cancer deaths in both men and women in the United States. The overall 5-year survival rate for all types of lung cancer is approximately 22%.

② Cigarette smoking is responsible for most lung cancers. Smoking cessation should be encouraged, particularly in those receiving curative treatment (ie, Stages I to IIIA non-small cell lung cancer [NSCLC] and limited-stage small cell lung cancer [SCLC]).

③ NSCLC is the most commonly diagnosed type of lung cancer (about 80%). NSCLC typically has a slower growth rate and doubling time than SCLC.

④ Annual screening with low-dose computed tomography (LDCT) imaging is recommended to identify lung cancer in high-risk individuals.

⑤ The treatment goals for lung cancer are cure (early-stage disease), prolonged survival, and maintenance of, or improved quality of life through alleviation of symptoms. Early-stage lung cancer has the highest cure rates, following surgical resection of the tumor with or without chemotherapy for NSCLC and chemoradiotherapy for SCLC.

⑥ Treatment decisions for NSCLC are guided by the stage of disease, histology (squamous or nonsquamous), targetable mutations such as epidermal growth factor (EGFR) exon 19 deletion or L858R, EGFR exon 20 insertion, Kirsten rat sarcoma viral oncogene homologue (KRAS), anablastyic lymphoma kinase (ALK), B-rapidly accelerated fibrosarcoma (BRAF), neurotrophic receptor kinase (NTRK), rearranged during transfection (RET), mesenchymal epithelial transition factor (MET), and receptor tyrosine kinase (ROS1), and programmed death ligand (PD-L1) expression levels of the tumor. Patient-specific factors (eg, performance status, comorbid conditions) must also be considered when developing a treatment plan.

⑦ Targeted therapies for advanced-stage NSCLC are preferred over platinum-based doublets or immunotherapy as first-line therapy in patients whose tumors harbor targetable genetic mutations such as EGFR exon 19 deletions or exon 21 (L858R) substitution mutations, EGFR exon 20 insertion mutations, or mutations in ALK, BRAF, NTRK, KRAS, MET, RET, or ROS1.

⑧ For patients without a targetable mutation, immunotherapy with anti-programmed-death 1 (PD-1) targeting monoclonal antibody is recommended as first-line treatment of metastatic NSCLC that is PD-L1 positive (tumor proportion score [TPS] ≥ 50%). Immunotherapy can be added to a platinum doublet in patients with tumors that do not have a targetable genetic mutation and/or are PD-L1 negative. Patients with extensive-stage SCLC may receive immunotherapy either with a platinum doublet as first-line therapy or alone as second-line therapy.

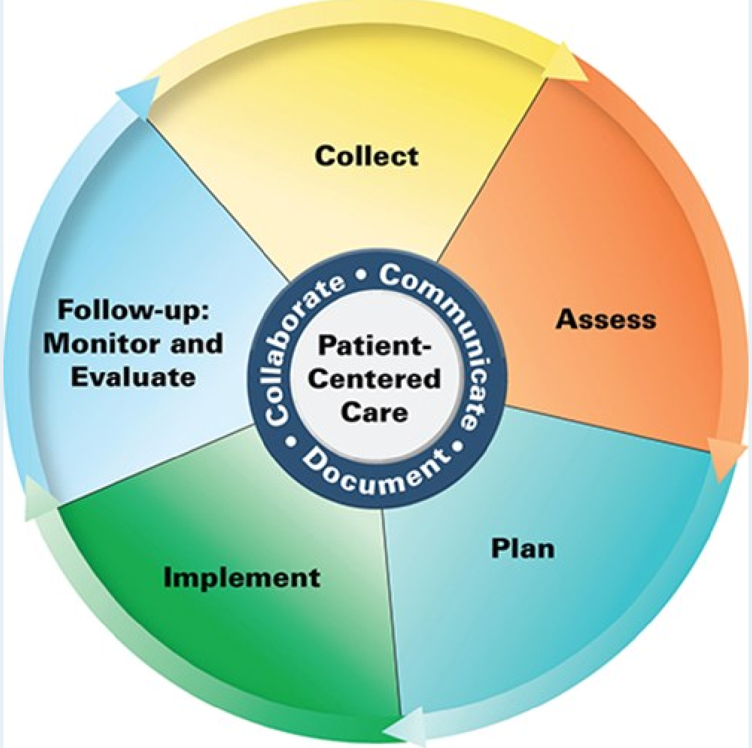
⑨ In the treatment of limited stage SCLC, thoracic radiation is always combined with chemotherapy and the regimen of choice is etoposide and cisplatin. Prophylactic cranial irradiation is added in patient who achieve a completion response.

⑩ Treatment approach for patients who experience relapsed SCLC include repeating initial chemotherapy regimen (if > 6 months since end of therapy) or second-line therapy with topotecan or lurbinectidin.

⑪ Optimal patient care includes the management of adverse drug reactions from drug therapy. Adverse drug reactions may cause delays in treatment administration, increase morbidity, and contribute to treatment failure.

PATIENT CARE PROCESS

Patient Care Process for Lung Cancer



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, ancestry)
- Patient history (past medical, family, social—dietary habits, tobacco use)
- Current medications and any prior anticancer therapy
- Symptoms of pain, pain score, pain management
- Clinical and objective evaluation of tumor status
- Objective data
  - BP, HR, height, weight, respiratory rate
  - Labs (eg, serum electrolytes, complete blood count, Scr, BUN)
  - Imaging scans (CT scan, endobrachial ultrasound)
  - Biopsy to obtain histology (Table 152-1) and biomarkers (PD-1, EGFR, ALK, etc.)

Assess

- Type of and response to any prior treatments
- Stage of tumor (Table 152-2)
- Anticancer treatment options based on the cancer's histology, stage, and biomarkers
- Need for any dose adjustments (renal/hepatic function, drug interaction)
- Adverse drug reactions from current anticancer regimen if this is second dose or second cycle

- Barriers to adherence for oral anticancer regimens
- Emotional status (eg, presence of anxiety, depression)

Plan*

- Goals of treatment (curative or palliative)
- Drug therapy regimen including drugs, dose, route, frequency, and duration (Tables 152-3–152-6)
- Supportive care plan (eg, antiemetics, premedications, infection prophylaxis, and medications for specific drugs [eg, folic acid and vitamin B_{12} for pemetrexed])
- Patient education (eg, treatment plan and schedule, adverse drug reactions and how to manage them)
- Provide tools to support adherence to anticancer treatments and supportive care medications
- Encourage use of a diary to track pain medication and diarrhea/constipation medications

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up for assessment of adverse drug reactions and timing of next cycle

Follow-up: Monitor and Evaluate

- Presence of adverse drug reactions
- Measure appropriate laboratory values to determine the presence of serious adverse drug reactions that warrant dose adjustments, delays, or discontinuation at the next cycle
- Assess for signs/symptoms of infection
- Inquire about pain symptoms
- Verify patient adherence to the treatment plan

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

View the video “Lung Cancer Screening” (https://youtu.be/hFPoYYKnEWw) from the American Cancer Society regarding the use of low-dose computed tomography (CT) scans for early detection in patients at an increased risk of lung cancer. What are some consequences of lung cancer screening in patients who are not at high risk for the disease? Consider the process for low-dose CT scan and the characteristics of appropriate candidates for screening. What are some difficulties patients may have while undergoing this exam? The information is useful to enhance understanding regarding the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION AND EPIDEMIOLOGY

① Lung cancer is a leading cause of morbidity and mortality. It has reached epidemic proportions in many industrialized countries and is the most common cause of cancer-related death in the world. About 236,740 new cases of lung cancer were diagnosed in the United States in 2022.[1] This represents a continued decline in new lung cancer diagnoses that began more than 30 years ago. Despite major advances in the understanding and management of lung cancer, the overall 5-year survival rate for lung cancer remains low at only 22%. In the United States, lung cancer accounts for about 12% of newly diagnosed cancers and is the leading cause of cancer death in adult men and women, with about 130,180 deaths in 2022. The incidence and mortality related to lung cancer are declining, which has been attributed to decreased tobacco use over the last 50 years as well as the development of new therapies. The incidence of lung cancer increases with age, with 61% of deaths occurring between ages 65 and 85 years.[1] Lung cancer incidence and mortality are higher in Black men and slightly lower in Black women compared to White counterparts.[1] The cure rate is highest with early-stage disease treated with surgical resection; however, most patients present with metastatic disease.[1]

Two leading oncology groups in the United States have published clinical practice guidelines for the treatment of lung cancer. The National Comprehensive Cancer Network (NCCN) has developed consensus-based guidelines that provide recommendations regarding the screening, staging, and treatment of both non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC).[2,3] The American Society of Clinical Oncology (ASCO) publishes several evidence-based guidelines that are regularly updated regarding the care of patients with lung cancer.[4,5] ASCO also has endorsed the guidelines of other organizations including guidelines on the use of molecular testing for NSCLC[6] and guidelines on the treatment of SCLC.[7]

ETIOLOGY

Lung carcinomas arise from normal bronchial epithelial cells that have acquired multiple genetic lesions and express a variety of phenotypes.[8] Important advances have been made in our understanding of the molecular genetic changes involved in lung cancer pathogenesis.[8] A large variety of molecular lesions result in the abrogation of key cellular regulatory and growth control pathways. Mutations cause activation of proto-oncogenes, inhibition of tumor suppressor genes, and production of autocrine (self-stimulatory) growth factors contributing to cellular proliferation and malignant transformation.[8]

Many of these molecular alterations are common to both SCLC and NSCLC, but certain mutations are found more frequently in specific subtypes of lung cancer and can be potentially treated with targeted interventions. In autocrine loop abnormalities, SCLC frequently overexpresses C-KIT, a protein tyrosine kinase receptor that is specific for stem cell factor. For NSCLC, multiple mutations have been identified that can drive tumor growth and survival. These biomarkers serve as targets of drug therapy. Multiple targetable mutations have been identified in NSCLC including EGFR, ALK, KRAS, BRAF, NTRK, MET, RET, ROS1, and HER2.[8–10]

② Smoking is a major cause of lung cancer, with about 80% of lung cancer deaths in the United States directly attributed to tobacco use. Tobacco smoke contains many substances, including tumor promoters, carcinogens, and cocarcinogens.[11] The association between environmental tobacco smoke (ETS; also referred to as passive smoking) and lung cancer risk in nonsmokers is clear. Studies show that spouses of smokers have a 25% higher risk of lung cancer than spouses of nonsmokers. In addition, workplace exposure to ETS increases the risk of lung cancer by about 17%. ETS contributes to about 3,000 lung cancers annually. Although these studies are observational, they consistently show a dose-risk relationship, with no safe level of exposure.[11] Smoking cessation is associated with a gradual decrease in the risk, but more than 5 years is necessary before an appreciable decline in risk occurs and the risk never returns to that of a nonsmoker.[11] Because of the public health implications, the United States has several tobacco control efforts, including antismoking campaigns, increased tobacco taxes, and smoke-free areas in many public areas. Although the prevalence of cigarette smoking has slowly decreased, it remains at about 14% in 2019.[12]

Although most cases of lung cancer are attributable to cigarette smoking, less than 20% of smokers develop lung cancer, suggesting other risk factors are relevant. An increased risk of lung cancer has been associated with exposure to other environmental respiratory carcinogens (eg, asbestos, benzene, and arsenic). Genetic risk factors are also important, with an increased risk of lung cancer observed in those with first-degree relatives diagnosed with the disease. Lung cancer risk is associated with polymorphisms that affect the expression and/or function of enzymes regulating the metabolism of tobacco carcinogens, DNA repair, or inflammation. Patients with a history of chronic obstructive airway disease and adults with asthma are at an increased risk of lung cancer.[8,10]

HISTOLOGIC CLASSIFICATION

Before treatment begins, it is critical that an experienced lung cancer pathologist reviews the pathologic material to confirm malignancy, characterize the tumor histology, and identify targetable molecular characteristics of the tumor.

③ NSCLC is diagnosed in most (80%) lung cancer patients. NSCLC typically has a slower growth rate and doubling time than SCLC. The histologic classification of NSCLC is well defined and widely accepted (Table 152-1).[13] Histologic types, subtypes, and identifiable variants provide information about the prognosis and can influence therapeutic decisions.[13,14]

TABLE 152-1

Histologic Classification of Non-Small Cell Lung Carcinomas

1. Squamous cell carcinoma
    - Papillary
    - Clear cell
    - Small cell
    - Basaloid
2. Adenocarcinoma
    - Minimally invasive adenocarcinoma
    - Invasive adenocarcinoma
    - Lepidic predominant (previously classified as bronchioalveolar carcinoma)
    - Acinar predominant
    - Papillary predominant
    - Micropapillary predominant
    - Solid predominant with mucin
    - Variants of invasive adenocarcinoma
    - Invasive mucinous adenocarcinoma (previously classified as bronchioalveolar carcinoma)
    - Colloid
    - Fetal (low and high grade)
    - Enteric
3. Large cell carcinoma
    - Large cell neuroendocrine carcinoma
    - Combined large cell neuroendocrine carcinoma
    - Basaloid carcinoma
    - Lymphoepithelioma-like carcinoma
    - Clear cell carcinoma
    - Large cell carcinoma with rhabdoid phenotype
4. Adenosquamous carcinoma
5. Sarcomatoid carcinomas
    - Pleomorphic carcinoma
    - Spindle cell carcinoma
    - Giant cell carcinoma
    - Carcinosarcoma
    - Pulmonary blastoma
    - Other
6. Carcinoid tumor
    - Typical carcinoid
    - Atypical carcinoid
7. Carcinomas of salivary gland type
    - Mucoepidermoid carcinoma
    - Adenoid cystic carcinoma
    - Epimyoepithelial carcinoma

Adapted from 2004 WHO classification and the 2011 IASCL/ATS/ERS classification.

Four major cell types of carcinomas (squamous cell, adenocarcinoma, large cell, and small cell) account for more than 90% of lung tumors. Early studies with localized disease demonstrated that radiation could cure SCLC, while surgery could not. Studies with the other histologic types demonstrated better outcomes with surgery than with radiation, which provided the basis for the general classification of SCLC and NSCLC. Historically, systemic treatment for NSCLC histologies was the same and resulted in a similar overall prognosis, which supported a general classification of SCLC and NSCLC. Incorporation of genetics in NSCLC and the availability of targeted therapies have led to personalized treatment. Optimal therapy requires knowledge of histology, immunotherapy marker expression, and genetic mutational status.[6,8]

Squamous cell carcinoma, one of the most common histologies of all lung cancers, now represents less than 30% of cases. It has a much higher incidence in males and smokers, with a strong dose-response relationship to tobacco exposure. Studies of the natural history of lung cancer in show a relatively constant tumor volume doubling time (104-122 days).[15] Squamous cell tumors are slower to metastasize with eventual spread to the hilar and mediastinal lymph nodes, liver, adrenal glands, kidneys, bone, and gastrointestinal tract.

Other histologies occurring in NSCLC are collectively referred to as nonsquamous NSCLC. Adenocarcinoma accounts for half of lung cancers and is increasing in frequency. It is the most common histology in nonsmoking patients. The natural history of adenocarcinoma in the lung shows that small tumors discovered through screening are relatively slow growing and tumor doubling time increases as they enlarge. Doubling time of tumors discovered with screening is about 576 days, while those found only with routine patient care grew more rapidly, doubling in size every 169 days.[15] This histology is likely to metastasize from a relatively small tumor (often before diagnosis) and spread widely to distant sites, including the contralateral lung, liver, bone, adrenal glands, kidneys, and CNS. Table 152-1 shows several subclassifications and variants of adenocarcinoma. Large cell carcinomas are infrequently occurring, undifferentiated epithelial tumors, which tend to be large and bulky tumors arising in the periphery of the lung. Large cell carcinomas have a propensity to metastasize in a pattern like adenocarcinomas and are associated with a similar prognosis.[3,10]

SCLCs account for 15% of all lung tumors. They are distinguished by their appearance as small cells with round to oval nuclei. Historically, SCLC was referred to as “oat cell” carcinoma due to its appearance. These tumors occur in major bronchi and the periphery of the lung. SCLC is aggressive and rapidly growing, with 60% to 70% of patients initially presenting with disease outside the hemithorax. SCLC commonly expresses neuroendocrine differentiation, which may account for some of the paraneoplastic syndromes frequently associated with this disease. SCLC secretes gastrin-releasing peptide that acts as an autocrine growth factor. The secretion of other peptide hormones, cytogenetic abnormalities, and amplification and increased expression of oncogenes are also common. SCLC typically metastasizes to the lymph nodes, opposite lung, liver, adrenal glands and other endocrine organs, bone, bone marrow, and CNS.[2,9] Unlike NSCLC, SCLC treatment is not guided by specific biomarkers due to their lack of clinical data demonstrating efficacy with targeted agents. However, genetic studies may be performed should new targeted therapies be developed.

Lung tumors can exhibit more than one cell type (eg, adenosquamous). Mixed histology tumors should also undergo genetic testing.[6,8] Patients can have multiple lung nodules arising in different lobes or the contralateral lung. This is referred to as synchronous tumors, and the nodules can be the same or different cell types. Synchronous tumors worsen overall prognosis.[3]

CLINICAL PRESENTATION

At the time of diagnosis, 16% of lung cancers are localized, 22% have regional spread, and 57% have distant metastases (some patients are not staged). Location and extent of the tumor determine presenting signs and symptoms. A lesion in the central portion of the bronchial tree is more likely to cause symptoms at an earlier stage as compared with a lesion in the periphery of the lung, which may remain asymptomatic until the lesion is large or has spread. The most common initial signs and symptoms include cough, dyspnea, and chest pain or discomfort, with or without hemoptysis.[10] Many patients with lung cancer also have chronic pulmonary and/or cardiovascular diseases (usually related to smoking), and such symptoms may go unnoticed or be attributed to concomitant diseases. Many patients also exhibit systemic symptoms of malignancy such as anorexia, weight loss, and fatigue. Disseminated disease can cause extrapulmonary signs and symptoms such as neurologic deficits resulting from CNS metastases, bone pain or pathological fractures secondary to bone metastases, or liver dysfunction resulting from tumor involvement in the liver.[10]

Paraneoplastic syndromes are signs and symptoms that occur at sites away from the tumor location(s) and are not associated with direct tumor involvement. They may be caused by the production of biologically active substances (eg, peptide hormones) or antibodies or by other undefined mechanisms. Paraneoplastic syndromes occur more frequently with lung cancer than with any other tumor, and more frequently with SCLC than with NSCLC. These syndromes may be the first signs of a tumor and may prompt the search for an underlying malignancy.[9]

CLINICAL PRESENTATION: Lung Cancer

Local signs and symptoms

- Cough
- Hemoptysis
- Dyspnea
- Rust-streaked or purulent sputum
- Chest, shoulder, or arm pain
- Wheeze and stridor
- Superior vena cava obstruction
- Pleural effusion or pneumonitis
- Dysphagia (secondary to esophageal compression)
- Hoarseness (secondary to laryngeal nerve paralysis)
- Horner’s syndrome
- Phrenic nerve paralysis
- Pericardial effusion/tamponade
- Tracheal obstruction

Extrapulmonary signs and symptoms

- Bone pain and/or pathologic fractures
- Liver dysfunction
- Neurologic deficits
- Spinal cord compression

Paraneoplastic syndromes

- Weight loss
- Cushing’s syndrome
- Hypercalcemia (most commonly in squamous cell lung cancer)
- Syndrome of inappropriate secretion of antidiuretic hormone (most commonly in SCLC)
- Pulmonary hypertrophic osteoarthropathy
- Clubbing
- Anemia
- Eaton-Lambert myasthenic syndrome

- Hypercoagulable state

SCREENING AND PREVENTION

④ Most patients with lung cancer have advanced disease at the time of diagnosis, which contributes to the poor prognosis associated with this disease. Surgery and radiation are the most effective treatment modalities in NSCLC and SCLC, respectively. Only patients diagnosed in early clinical stage can be cured with these treatment modalities alone.[2,3,16,17] The need to diagnose lung cancer earlier provides rationale for screening.

The survival benefits of screening with low-dose computed tomography (LDCT) were first documented in the National Lung Cancer Screening Trial, which enrolled more than 54,000 high-risk smokers. Screening discovered 70% of tumors at stage I or II, when they were potentially curable with surgical resection. The study reported a decrease in overall mortality (7% vs 7.5%) and lung cancer-specific mortality (1.3% vs 1.7%) with LDCT versus control.[18]

The evidence-based recommendation is to offer annual screening with LDCT to high-risk individuals, defined as aged 50 to 80 years with a 20-pack-year history who are still smoking or have quit for less than 15 years.[19] This recommendation comes with a few caveats, including the fact that the most important step is for current smokers to quit. Follow-up trials to the National Lung Cancer Screening Trial validated the earlier onset of screening[20] and the pack year criteria.[21]

C*hemoprevention* (the use of prophylactic medications to prevent the development of cancer) has failed to show benefit for lung cancer. Many studies of potential chemopreventive agents, including nonsteroidal anti-inflammatory drugs, retinoids, inhaled glucocorticoids, vitamin E, selenium, and green tea extracts, have been conducted, but none have been successful.[22] In summary, the most effective prevention/early intervention approach is to avoid tobacco, maintain a healthy diet with high amounts of fruits and vegetables, and offer screening to high-risk individuals.

DIAGNOSIS

A patient suspected of having lung cancer should undergo a diagnostic evaluation. Diagnosis of lung cancer requires visualization of the cancerous lesion and tissue sampling for pathologic assessment. Patients must have a thorough history and physical examination with emphasis on detecting signs and symptoms of the primary tumor, regional spread, distant metastases, and paraneoplastic syndromes. Performance status should be assessed to determine if a patient is a candidate for aggressive therapy.[2,3,9,10]

Visualization of suspected tumor(s) provides information necessary to choose the most appropriate sampling technique. Computed tomography (CT) scans of the chest and upper abdomen are the most common initial radiologic evaluations. The staging workup can include an endobronchial ultrasound, positron emission tomography (PET) scan, or other tests.[9,10] The use of integrated CT-PET technology has been reported to improve the diagnostic accuracy in the staging of NSCLC over either test alone.[10]

Once located, pathologic examination of tumor tissue is necessary to establish the diagnosis of lung cancer. Tissue is usually obtained through the least invasive method most likely to result in an adequate sample; methods include sputum cytology, tumor biopsy by bronchoscopy, mediastinoscopy, percutaneous needle biopsy, or open lung biopsy. The tissue sample not only confirms malignancy, it is also necessary to determine the specific tumor type and to provide tissue for molecular analysis including testing for PD-L1 and genetic mutations that drive tumor growth.[4,5] Once the diagnosis is established, additional radiologic tests may be required to evaluate lymph nodes and potential metastatic sites for complete staging.[2,3,9,10]

STAGING

Once the diagnosis of lung cancer is confirmed, the extent of disease must be determined to estimate prognosis and guide therapy. For NSCLC, tumor growth and spread are staged with the American Joint Committee on Cancer, tumor, node, and metastasis (TNM) staging system. SCLC is typically staged with the Veterans Administration Lung Cancer Study Group method.[13,23]

Non-Small Cell Lung Cancer

Clinical staging of NSCLC with the TNM system incorporates the size of the tumor, extent of nodal involvement, and presence of metastatic sites.[13] Clinical stages and associated survival rates are described in Table 152-2. For comparison of various therapeutic modalities, a simpler stage grouping system is used in which stage I refers to tumors confined to the lung without lymphatic spread, stage II refers to large tumors with ipsilateral peribronchial or hilar lymph node involvement, stage III includes other lymph node and regional involvement that may or may not involve both lungs, and stage IV includes tumor with distant metastases. Local disease is associated with the highest cure and survival rates, while advanced disease results in 5-year survival of less than 5%. Once evidence of metastatic disease has been identified, further evaluation is not necessary.

TABLE 152-2

Tumor (T), Node (N), Metastasis (M) Staging for Non-Small Cell Lung Cancer

Primary Tumor (T		**Description**
T_1		Tumor ≤3 cm in diameter, surrounded by lung or visceral pleura, without invasion more proximal than lobar bronchus
	T_{1mi}	Minimally invasive adenocarcinoma: adenocarcinoma (≤3 cm in diameter) with a predominately lepidic pattern
	T_{1a}	Tumor ≤1cm in diameter
	T_{1b}	Tumor >1 cm but ≤2 cm in diameter
	T_{1c}	Tumor >2 cm but ≤3 cm in diameter
T_2		Tumor >3 cm but ≤5 cm, or tumor with any of the following features: - Involves main bronchus, without involvement of the carina - Invades visceral pleura - Associated with atelectasis or obstructive pneumonitis that extends to the hilar region, involving part or all of the lung
	T_{2a}	Tumor >3 cm but ≤4 cm
	T_{2b}	Tumor >4 cm but ≤5 cm
T_3		Tumor >5 cm but ≤7 cm or directly invading the parietal pleura, chest wall, phrenic nerve, parietal pericardium, or with separate tumor nodule(s) in the same lobe as the primary tumor
T_4		Tumor >7 cm or tumor of any size that invades the diaphragm, mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina, or with separate tumor nodules in a different ipsilateral lobe
Regional Lymph Nodes (N)		
N_0		No regional lymph node metastases
N_1		Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N_2		Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)

N_3		Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
Distant Metastasis (M)		
M_0		No distant metastasis
M_1		Distant metastasis
	M_{1a}	Separate tumor nodule(s) in a contralateral lobe; tumor with pleural or pericardial nodules, or malignant pleural or pericardial effusion
	M_{1b}	Single extrathoracic metastasis in a single organ (including involvement of a single nonregional node)
	M_{1c}	Multiple extrathoracic metastases

Stage	T	N	M	5-Year Survival (%)
IA1	T_{mi}-T_{1a}	N_0	M_0	92%
IA2	T_{1b}	N_0	M_0	83%
IA3	T_{1c}	N_0	M_0	77%
IB	T_{2a}	N_0	M_0	68%
IIA	T_{2b}	N_0	M_0	60%
IIB	T_{1a}, T_{1b}, T_{1c}, T_{2a}, T_{2b}	N_1	M_0	53% (All IIB)
	T_3	N_0	M_0	
IIIA	T_{1a}, T_{1b}, T_{1c}, T_{2a}, T_{2b}	N_2	M_0	36% (all IIIA)
	T_3	N_1	M_0	
	T_4	N_0, N_1	M_0	
IIIB	T_{1a}, T_{1b}, T_{1c}, T_{2a}, T_{2b}	N_3	M_0	26% (all IIIB)
	T_3, T_4	N_2	M_0	
IIIC	T_3, T_4	N_3	M_0	13%
IVA	Any T	Any N	M_{1a} or M_{1b}	10%
IVB	Any T	Any N	M_{1c}	<1%

Small Cell Lung Cancer

The most commonly used system of staging SCLC was developed originally by the Veterans Administration Lung Cancer Study Group.[23] This system categorizes SCLC into two stages: limited and extensive disease. When evidence of the tumor is confined to a single hemithorax and can be encompassed by a single radiation field, the disease is considered limited. Progression beyond this point is extensive disease. About 60% to 70% of patients initially present with extensive-stage disease. The initial pretreatment evaluation of an SCLC patient should include a medical history, a clinical examination, and laboratory survey, as well as a CT scan of the chest, abdomen, and head. The typical approach is to identify tumor spread that would demonstrate extensive stage, at which time the workup can stop. For patients without extrathoracic disease, a bone scan and bone marrow biopsy should be performed to confirm limited-stage disease.[2,9]

TREATMENT

Desired Outcomes

⑤ The treatment goals for lung cancer include cure, prolonged survival when cure is not possible, and maintenance of/improved quality of life through symptom alleviation. The ability to achieve these goals depends on tumor histology, extent of disease, and patient characteristics such as age, history, and performance status.[2,3] Stages I and II (NSCLC) or limited-stage (SCLC) diseases are commonly referred to as early-stage disease, while stages III and IV (NSCLC) or extensive-stage (SCLC) diseases are referred to as advanced-stage disease. In patients with early-stage disease who can tolerate aggressive treatment, a definitive cure is the desired outcome of treatment. In patients with advanced-stage disease who can tolerate aggressive therapy, the desired outcome is prolongation of survival. Regardless of treatment goals, all therapies should improve quality of life. Patients should carefully weigh the potential benefits of treatment against the significant toxicities associated with an aggressive approach. Treatment decisions must include the healthcare team and an informed, well-counseled patient.

Non-Small Cell Lung Cancer

⑥ If left untreated, patients with advanced NSCLC will die within months.[10] Surgery, radiation, and systemic therapies with cytotoxic chemotherapy, immunotherapy, or targeted therapies are used in the management of NSCLC. The applications of these treatment modalities are determined by stage- and patient-specific factors.[3,10]

Local Disease (Stage I-II)

Local disease is associated with a favorable prognosis and the treatment goal is cure. A multimodal approach involving surgery, radiation, and systemic treatments is utilized for early-stage disease. Surgery is the primary treatment and may be used alone or in combination with radiation and/or systemic therapy.[3] Patients who are not surgical candidates or refuse surgical interventions can be treated with radiation, although cure rates are lower. Stage IA and IB tumors are treated with surgery.[3,24] If surgical margins are positive, re-resection is recommended. Alternatively, patients may receive radiotherapy with or without chemotherapy. Although controversial, patients with IB tumors and high-risk features (eg, poorly differentiated tumors, vascular invasion, large tumors, visceral pleural involvement) may also receive adjuvant chemotherapy.[3,24,25]

The primary treatment of stage IIA and IIB diseases is surgery followed by adjuvant chemotherapy, typically for four cycles. The optimal adjuvant chemotherapy regimen is not clear. Positive clinical trials used platinum-based regimens, with arguably the best clinical trial data coming from cisplatin–vinorelbine (Table 152-3).[14] The absolute benefit in 5-year overall survival ranges from no benefit to 15%, with a recent systematic review reporting an absolute difference of 4%. The analysis suggested little effect of the chemotherapy regimen.[14] Although genetics and histology influence systemic treatment and outcomes in advanced disease, this approach has not been tested in large, randomized trials of adjuvant chemotherapy.

TABLE 152-3

Common Chemotherapy Regimens Used in the Adjuvant Treatment of Non-Small Cell Lung Cancer

Regimen	Drugs and Doses	Frequency and Number of Cycles
Cisplatin/etoposide	Cisplatin 100 mg/m^2 IV day 1 Etoposide 100 mg/m^2 IV daily on day 1, 2, and 3	Every 28 days for 4 cycles
Cisplatin/vinorelbine	Cisplatin 50 mg/m^2 IV day 1 and 8 Vinorelbine 25 mg/m^2 IV day 1, 8, 15, and 22	Every 28 days for 4 cycles
	Cisplatin 100 mg/m^2 IV day 1 Vinorelbine 30 mg/m^2 IV day 1, 8, 15, and 22	Every 28 days for 4 cycles
Carboplatin/paclitaxel	Carboplatin AUC 6 IV day 1 Paclitaxel 200 mg/m^2 IV day 1	Every 21 days for 4 cycles
Cisplatin/pemetrexed	Cisplatin 75 mg/m^2 IV day 1 Pemetrexed 500 mg/m^2 IV day 1	Every 21 days for 4 cycles (for nonsquamous histology only)

The benefits of adjuvant targeted therapy in patients who have undergone a complete resection of their NSCLC has been identified. In patients with stage Ib to IIIa disease whose tumors test positive for sensitizing EGFR mutations, the kinase inhibitor, osimertinib, improved 2-year disease-free survival from 52% to 89% compared to placebo.[26] Benefit was demonstrated in patients regardless of chemotherapy use after surgery. The study was planned for a 3-year duration of treatment; however, it was stopped early due to clinical benefit, leaving the optimal duration of therapy in the adjuvant setting unknown. In patients whose tumors have a PD-L1 expression of at least 1%, 1 year of adjuvant therapy with the PD-L1 inhibitor, atezolizumab, following complete resection and chemotherapy for the treatment of stage II-IIIA NSCLC, resulted in improved disease-free survival at 2 years (74.6% vs 61.0%) and at 3 years (60% vs 48.2%).[27] It is important to note atezolizumab is not approved for use in patients with stage IB disease. Targeted therapies are discussed in further detail in the section of this chapter covering treatment of advanced stage and relapsed NSCLC, information on proper dosing can be found in Tables 152-4 and 152-5.

Some patients with early-stage NSCLC receive neoadjuvant therapy, therapy before surgery. Such patients could include those with tumors that are considered operable but may be difficult to resect due to the tumors size, location, involvement of other structures, or extent of lymph node involvement. Typically, these patients would receive the same regimens used in the adjuvant setting, but given before surgery. The addition of immunotherapy to chemotherapy in this setting improves outcomes. In patients with resectable NSCLC with a tumor size greater than 4 cm or having positive lymph node involvement, adding the PD-L1 inhibitor nivolumab to standard chemotherapy every 3 weeks for 3 cycles improves the median event free survival (31.6 vs 20.8 months) and rate of pathologic complete response prior to surgery (24% vs 2.2%).[28] The use of adjuvant targeted therapy in patients received neoadjuvant nivolumab has not been studied.

Adjuvant radiation should generally be avoided in patients with local disease who have complete resection and clean margins as it does not improve survival. However, radiation, or more commonly chemoradiotherapy, can be indicated in specific situations. Patients who are medically inoperable should receive chemoradiotherapy if they can tolerate the combined modality. Patients who have positive margins after resection should ideally undergo “re-resection”; if that is not possible, then radiation to the positive margin(s) with or without chemotherapy can be given. Concurrent rather than sequential administration of chemotherapy and radiation therapy is preferred when both are used.[3] Recommended regimens combined with radiation include cisplatin with either gemcitabine or docetaxel for patients with squamous histology or cisplatin combined with pemetrexed in patients with non-squamous histology. Carboplatin may be substituted in patients who cannot tolerate cisplatin.

Locally Advanced Disease (Stage III)

Patients with more advanced local disease have large tumors, multiple tumors, and/or nodal involvement. This group of patients is heterogeneous, and few large clinical trials are available to guide treatment. Treatment is best planned by a multidisciplinary team where individual features and patient preferences are considered. Optimal outcomes are achieved with multimodality therapy that typically includes systemic chemotherapy. For patients with stage III disease (large tumor [T_3 or T_4] or mediastinal node positive), radiation in the adjuvant or neoadjuvant setting with or without chemotherapy is recommended. Patients with operable disease should be considered for surgery preceded or followed by systemic chemotherapy. Adjuvant chemotherapy after surgery prolongs overall survival in patients with completely resected stage III disease (Table 152-3).[3,14] Two meta-analyses have reported that neoadjuvant chemotherapy improves 5-year survival by 5% compared to surgery alone.[29,30] The stage most likely to benefit, what regimen is best, or how it would compare to surgery followed by adjuvant therapy were not evaluated. The potential benefit of reducing tumor size to make the surgery more feasible is attractive for patients with large tumors. A trial of neoadjuvant versus adjuvant therapy has not been reported; however, both approaches are equivalent and superior to surgery alone.[3] If neoadjuvant chemotherapy is to be utilized in stage III disease, consideration should be given to the inclusion of nivolumab as described earlier.

Radiation may be given in place of surgery as the local treatment modality combined with chemotherapy. Although a large definitive trial has not been performed to compare radiation and surgery in this subset of patients, several small randomized trials have shown no difference in outcomes, such as overall survival, event-free survival and local failure rates.[31,32] Therefore, it is recommended that patients with resectable stage IIIA NSCLC be treated with chemotherapy followed by surgery or radiation, depending on patient and tumor features.[3,24] As with local disease, the use of targeted therapy with atezolizumab or osimertinib with appropriate biomarker expression is recommended for patients with resectable stage IIIa disease.

Patients with stage IIIA disease who are not surgical candidates are typically treated with both a platinum-containing regimen and concurrent radiotherapy. Patients with tumors that cannot fit safely in a radiation field may receive induction chemotherapy followed by chemoradiotherapy. Responding patients may then become surgical candidates.

Stage IIIB and IIIC NSCLC are generally considered unresectable. These patients should receive induction therapy with chemoradiation. Patients who respond to chemoradiation (about 80% of patients) should then receive consolidation therapy with the PD-L1 inhibitor, durvalumab, for 1 year. In a large clinical trial, durvalumab demonstrated significantly sustained benefits over placebo in progression-free survival (16.9 vs 5.6 months) and overall survival (47.5 vs 29.1 months).[33] Durvalumab should not be used if a patient undergoes surgical resection. Patients with stage III disease who are not candidates for radiation are treated like those with stage IV disease.[3–5,24]

Advanced (Stage IV) and Relapsed Disease

About 56% of NSCLC patients have advanced disease (stage IV) at diagnosis.[1,3,10] Typically, these patients are not surgical candidates; however, those who harbor a single metastatic site may undergo resection of the primary tumor and the metastatic site.[4,5] Chemoradiotherapy can be considered for patients with a tumor that fits in a tolerable radiation field. However, for most patients systemic therapy is the primary treatment modality.

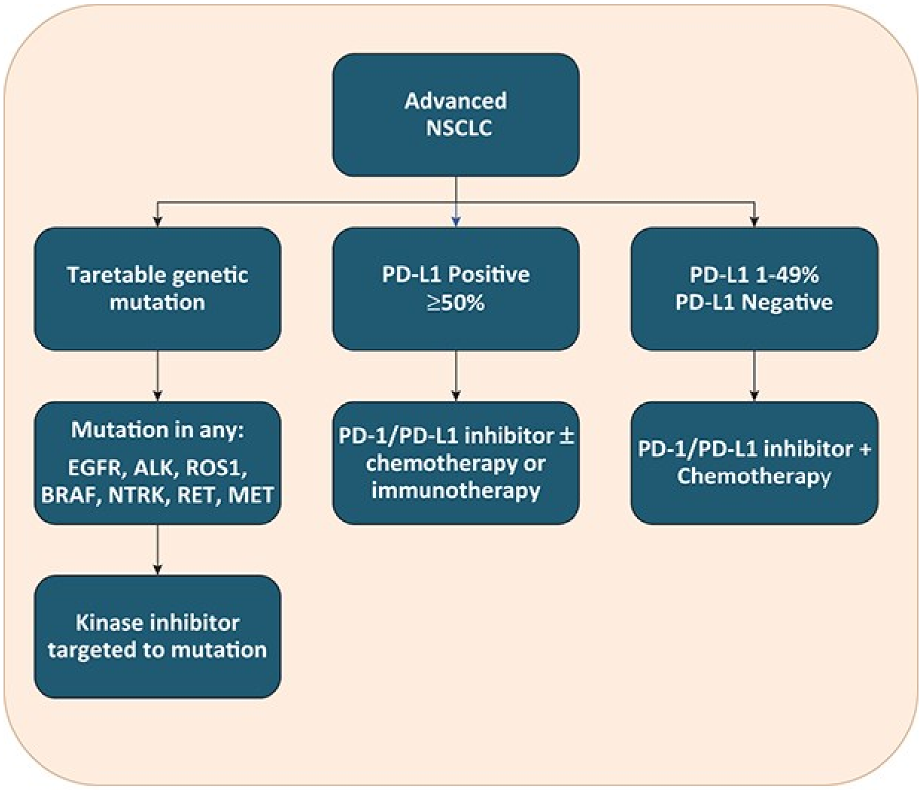
The treatment approach for NSCLC that has relapsed after initial treatment of localized disease is like the approach used for patients who have stage IV disease at diagnosis. The goal of initial therapy is to palliate symptoms, improve quality of life, and increase survival. Therapy for advanced-stage NSCLC depends on patient-specific factors and tumor characteristics.

The most important patient-specific factor is performance status, as described in Chapter 149, "Cancer: The Disease and Treatment." Patients with an Eastern Cooperative Oncology Group (ECOG) performance status of 0 to 2 are most likely to derive benefit from intensive treatment. Patients with significant comorbidities should be considered for less intensive therapy (eg, single-agent therapy). Patients with poor ECOG performance status (3 or 4) do not respond well to chemotherapy and have a high likelihood of toxicity and should receive best supportive care and palliative radiation when necessary.[4,5]

Three pathways have been identified for advanced NSCLC: (1) targetable genetic mutation-driven, which is further divided based on the sensitizing mutation (eg, EGFR, ALK), (2) immune sensitive (PD-L1+), and (3) nonbiomarker-driven therapy treatment, which is further classified as squamous histology or nonsquamous histology due to drug toxicity and efficacy (Fig. 152-1). Unlike tumors of nonsquamous histology, tumors of squamous histology do not usually harbor targetable genetic mutations. Testing for these mutations in squamous tumors is encouraged, but optional. However, like other histologies of NSCLC, squamous histology tumors should have PD-L1 testing to determine sensitivity to first-line immunotherapy.[3,8,10]

FIGURE 152-1

Algorithm for initial treatment of advanced-stage NSCLC.



Advanced NSCLC
Taretable genetic mutation
PD-L1 Positive ≥50%
PD-L1 1-49% PD-L1 Negative
Mutation in any: EGFR, ALK, ROS1, BRAF, NTRK, RET, MET
PD-1/PD-L1 inhibitor ± chemotherapy or immunotherapy
PD-1/PD-L1 inhibitor + Chemotherapy
Kinase inhibitor targeted to mutation

PD-L1 expression is tested with an immunohistochemistry assay; as it relates to treatment selection, a tumor is PD-L1+ if 1% or more of the viable tumor cells stain positive for PD-L1 expression (TPS ≥1%). Testing for targetable genetic mutations identifies tumors that harbor sensitizing mutations that respond to targeted therapies. Selected treatments for each group are listed in Table 152-4.

TABLE 152-4

Selected Regimens for the Treatment of Advanced-Stage Non-Small Cell Lung Cancer

	Nonsquamous		**Squamous**	
Place in Therapy	PD-L1 ≥ 50%	PD-L1 1-49%	PD-L1 ≥ 50%	PD-L1 1-49%
First Line	Pembrolizumab 200 mg IV on day 1 every 21 days or 400 mg IV on day 1 every 42 days Repeat until disease	Platinum + pemetrexed + pembrolizumab Cisplatin 75 mg/m^2 or Carboplatin AUC 5 IV on day 1 Pemetrexed 500 mg/m^2 IV on day 1 Pembrolizumab 200 mg IV on day 1	Pembrolizumab 200 mg IV on day 1 every 21 days or 400 mg IV on day 1 every 42 days Repeat until disease progression, or	Carboplatin + paclitaxel + pembrolizumab Carboplatin AUC 6 IV on day 1 Paclitaxel 200 mg/m^2 IV on day 1 or nab-paclitaxel 100 mg/m^2 IV on day 1,8, and 15 Pembrolizumab 200 mg IV on day 1

	progression or unacceptable toxicity for a maximum of 2 years	Repeat cycle every 3 weeks × 4 cycles—Pembrolizumab maintenance up to 31 additional doses or until progression	unacceptable toxicity for a maximum of 2 years	Repeat cycle every 3 weeks × 4 cycles–Pembrolizumab maintenance up to 31 additional doses or until progression
	Atezolizumab 840 mg IV on day 1, repeat every 14 days or 1,200 mg IV on day 1 repeat every 21 days or 1,680 mg IV on day 1 repeat every 28 days Continue until disease progression or unacceptable toxicity	Atezolizumab + carboplatin + paclitaxel + bevacizumab Atezolizumab 1,200 mg IV on day 1 Carboplatin AUC 6 IV on day 1 Paclitaxel 200 mg/m^2 IV on day 1 Bevacizumab 15 mg/kg IV on day 1 Repeat cycle every 3 weeks × 6 cycles Atezolizumab and bevacizumab maintenance until progression	Carboplatin + taxane + pembrolizumab Carboplatin AUC 6 IV on day 1 Paclitaxel 200 mg/m^2 IV on day 1or nab-paclitaxel 100 mg/m^2 IV on day 1, 8, and 15 Pembrolizumab 200mg IV on day 1 Repeat cycle every 3 weeks × 4 cycles Pembrolizumab maintenance up to 31 additional doses or until progression	Nivolumab + ipilimumab + carboplatin + paclitaxel Nivolumab 360 mg IV on day 1 and 22 Ipilimumab 1 mg/kg IV on day 1 Paclitaxel 200 mg/m^2 on day 1 and 22 Carboplatin AUC 6 IV on day 1 and 22 Followed by nivolumab and ipilimumab maintenance every 42 days until disease progression or unacceptable toxicity for a maximum of 2 years
	Cemiplimab 350 mg IV on day 1 Repeat every 21 days until disease Continue until disease progression or unacceptable toxicity	Nivolumab + ipilimumab + platinum+ pemetrexed Nivolumab 360 mg IV on days 1 and 22 Ipilimumab 1 mg/kg IV on day 1 Pemetrexed 500 mg/m^2 on days 1 and 22 Carboplatin AUC 6 IV or cisplatin 75 mg/m^2 on day 1 and 22 Followed by nivolumab and ipilimumab maintenance every 42 days until disease progression or unacceptable toxicity for a maximum of 2 years	Atezolizumab 840 mg IV on day 1, repeat every 14 days or 1,200 mg IV on day 1 repeat every 21 days or 1,680 mg IV on day 1 repeat every 28 days Continue until disease progression or unacceptable toxicity	Nivolumab + ipilimumab Nivolumab 3 mg/kg IV on day 1, 15, and 29 Ipilimumab 1 mg/kg IV on day 1 Repeat every 42 days until disease progression or unacceptable toxicity for a maximum of 2 years
	Platinum + pemetrexed + pembrolizumab	Nivolumab + ipilimumab Nivolumab 3 mg/kg IV on day 1, 15, and 29	Cemiplimab 350 mg IV on day 1	Pembrolizumab 200 mg IV on day 1 every 21 days or

	Cisplatin 75 mg/m^2 or carboplatin AUC 5 IV on day 1 Pemetrexed 500 mg/m^2 IV on day 1 Pembrolizumab 200 mg IV on day 1 Repeat cycle every 3 weeks × 4 cycles Pembrolizumab maintenance up to 31 additional doses or until progression	Ipilimumab 1 mg/kg IV on day 1 Repeat every 42 days until disease progression or unacceptable toxicity for a maximum of 2 years	Repeat every 21 days until disease progression or unacceptable toxicity	400 mg IV on day 1 every 42 days Repeat until disease progression, or unacceptable toxicity for a maximum of 2 years
First-line: Contraindications to PD-1 or PD-L1 Inhibitors	Carboplatin + pemetrexed Carboplatin AUC 5 IV on day 1 Pemetrexed 500 mg/m^2 IV on day 1 Repeat cycle every 3 weeks × 4 or 6 cycles followed by pemetrexed maintenance		Gemcitabine + cisplatin Gemcitabine 1,000 mg/m^2 IV on day 1, 8, and 15 Cisplatin 100 mg/m^2 IV on day 1 Repeat cycle every 28 days	
Second Line: No previous checkpoint inhibitor	Nivolumab 240 mg IV on day 1 repeat every 14 or 480 mg IV on day 1 repeat every 28 days Continue until disease progression or unacceptable toxicity			
	Atezolizumab 840 mg IV on day 1, repeat every 14 days or 1,200 mg IV on day 1 repeat every 21 days or 1,680 mg IV on day 1 repeat every 28 days Continue until disease progression or unacceptable toxicity			
	Pembrolizumab 200 mg IV on day 1 every 21 days or 400 mg IV on day 1 every 42 days Repeat until disease progression, or unacceptable toxicity			
Second Line: Other recommend	Docetaxel + ramucirumab Docetaxel 75 mg/m^2 IV day 1 Ramucirumab 10 mg/kg IV day 1 Repeat every 21 days			

Targetable Genetic Mutation

⑦ Patients with advanced lung cancer with confirmed positive for targetable genetic driver mutation have several treatment options based on the specific mutation: EGFR, KRAS, ALK, ROS1, $\text{BRAF}^{\text{V600E}}$, METex14 skipping, NTRK, or RET-fusion. Genetic testing of tumors should be performed at the time of diagnosis in all patients, including those with localized disease.[3,5]Adverse drug reactions and monitoring parameters of select oral targeted therapies used in NSCLC are included in Table 152-5.

TABLE 152-5

Selected Oral Targeted Therapies for Advanced, Mutation-Driven NSCLC

Drug and Dosing	**Adverse Reactions**		**Monitoring Parameters**	**Comments**
	Common	**Rare But Serious**		
EGFR Exon 19 Deletion or *EGFR l858R* Mutation				
Osimertinib 80 mg (1 × 80 mg tablet) once daily	• Anorexia • Dermatologic reactions including dry skin and rash • Diarrhea • Fatigue • Myelosuppression • Paronychia • Stomatitis	• Cardiomyopathy • Interstitial lung disease • Keratitis • QTc Interval prolongation	• Signs and symptoms of interstitial lung disease (dyspnea, cough, and fever) • Skin exam • CMP at baseline and periodically • Ophthalmic exam periodically and at the onset of any vision changes • CBC at baseline and periodically • ECG periodically in patients with congenital long QTc syndrome, heart failure, electrolyte abnormalities, or concomitantly receiving other QT prolonging agents • Ejection fraction at baseline and periodically in patients at risk for developing heart failure or if patients develop cardiac symptoms	• Can be taken without regard to meals • Increase dose by 50% if patient taking strong cytochrome P4503A4 inducer • Activity not effected by T790M mutation • Improved CNS activity compared to other EGFR targeting agents • Can be used in patients who have progressed while receiving earlier generation inhibitors (erlotinib, gefitinib, dacomitinib)
Erlotinib 150 mg (1 × 150 mg tablet) once daily	• Anorexia • Cough • Fatigue • Diarrhea • Dyspnea • Nausea and vomiting • Rash	• Cerebrovascular accident • Gastrointestinal perforation • Hemolytic anemia with thrombocytopenia • Hepatotoxicity including	• Signs and symptoms of interstitial lung disease • Skin exam • CMP at baseline and periodically • Ophthalmic examinations periodically and at the onset of any changes in vision • Signs and symptoms of	• Should be taken 1 hour before or 2 hours after meals • Best absorbed in acidic gastric environment • Cytochrome P450 3A4 substrate, use with caution with 3A4 inducers/inhibitors

		hepatorenal syndrome - Interstitial lung disease - Ocular disorders including corneal perforation, ulceration, or severe keratitis - Severe rash, including Stevens-Johnson Syndrome and toxic epidermal necrolysis	hemorrhage if patients receiving warfarin	- Increased hemorrhage risk with warfarin - Resistance caused by T790M mutation - Has been studied in combination with bevacizumab or ramucirumab
Afatinib 40mg (1 × 40 mg tablet) once daily	- Anorexia - Dermatologic reactions including dry skin and rash - Diarrhea - Nausea and vomiting - Paronychia - Pruritus - Stomatitis	- Hepatotoxicity - Interstitial lung disease - Keratitis Renal impairment from dehydration due to diarrhea - Severe rash, including Stevens-Johnson syndrome and toxic epidermal necrolysis	- Signs and symptoms of interstitial lung disease - Skin exam - CMP at baseline and periodically - Ophthalmic examinations periodically and at onset of any changes in vision	- Should be taken 1 hour before or 2 hours after meals - Dose reduction recommended for severe renal impairment - Diarrhea can be severe and require dose reductions - Pharmacokinetics may be affected by P-glycoprotein inhibitors and inducers - Resistance caused by T790M mutation - Patients with reduced ejection fraction excluded from clinical trials
ALK Rearrangement				
Alectinib 600 mg (4 × 150 mg capsules) twice daily	- Anemia - Constipation - Edema - Fatigue - Hepatotoxicity - Leukopenia - Myalgia - Photosensitivity	- Bradycardia - Endocarditis - Gastrointestinal perforation - Increased creatine kinase - Interstitial lung disease - Pulmonary	- Signs and symptoms of interstitial lung disease - CMP at baseline and periodically - CBC with differential monthly - Liver function tests every 2 weeks for the first 3 months of treatment then monthly - Heart rate and blood pressure	- Should be taken with meals - Counsel regarding appropriate precautions to protect from UVA/UVB exposure

		embolism • Renal impairment	should be monitored regularly • CPK every 2 weeks for the first month of treatment and with patient reports of unexplained muscle pain, tenderness, or weakness.	
Brigatinib 90 mg (1 × 90 mg tablet) orally once daily for 7 days then increase to 180 mg (1 × 180 mg tablet daily if tolerated	• Cough • Diarrhea • Fatigue • Hyperglycemia • Increased creatine kinase • Increased serum lipase and amylase • Nausea	• Bradycardia • Hypertension • Interstitial lung disease • Pneumonitis, including pneumonia • Visual disturbances	• Signs and symptoms of interstitial lung disease • Ophthalmic examinations periodically and at the onset of any changes in vision • Blood pressure should be monitored after 2 weeks then monthly • Heart rate and blood pressure should be monitored regularly • CPK levels should be monitored regularly • Fasting serum glucose at baseline and regularly • Lipase and amylase levels monitored regularly	• Can be taken without regard to meals • Dose reduction recommended for severe renal or hepatic impairment • Cytochrome P450 3A4 substrate, should not be used with moderate-to-strong inhibitors or inducers of 3A4
Lorlatinib 100 mg (1 × 100 mg tablet) once daily	• Arthralgia • Diarrhea • Dyslipidemia • Dyspnea • Edema • Fatigue • Peripheral neuropathy • Weight gain	• Atrioventricular block • CNS effects such as mood disorders or seizures • Hepatotoxicity • Hyperglycemia • Hypertension • Interstitial lung disease	• Signs and symptoms of interstitial lung disease • Blood pressure should be monitored after 2 weeks then monthly • Heart rate and blood pressure should be monitored regularly • Fasting serum glucose at baseline and regularly • Serum cholesterol and triglycerides at baseline, 1 month and 2 months after initiation then periodically • ECG at baseline and periodically	• Can be taken without regard to meals • Dose reduction recommended for severe renal impairment • Has demonstrated efficacy after the failure of previous ALK targeted therapies • Patients with severe psychiatric illness excluded from clinical trials
ROS1 Rearrangement				
Crizotinib 250 mg (1 × 250 mg capsule) twice daily	• Anorexia • Constipation • Diarrhea • Dizziness • Edema • Fatigue • Hepatotoxicity	• Bradycardia • Interstitial lung disease • Pulmonary embolism • QTc Interval prolongation	• Signs and symptoms of interstitial lung disease • CMP at baseline and periodically • Ophthalmic evaluation in patients with new-onset vision changes	• Can be taken without regard to meals • Dose reduction recommended for severe renal or hepatic impairment • Cytochrome P450 3A4

	Lymphopenia and neutropenia Nausea and vomiting Neuropathy Upper respiratory infection, including possible pneumonia Vision disorders		CBC with differential monthly ECG should be monitored periodically in patients with heart failure, bradyarrhythmias, electrolyte abnormalities, or concomitantly receiving other QT prolonging agents Heart rate and blood pressure should be monitored regularly	substrate, should not be used with strong inhibitors or inducers of 3A4 Fatal hepatoxicity has occurred Ocular toxicity can lead to severe vision loss
Entrectinib 600 mg (3 × 200 mg capsules) once daily	Arthralgia/myalgia Constipation Edema Fatigue Nausea/vomiting/diarrhea Vision disorders Weight gain	Fractures Heart failure Hepatoxicity Hyperuricemia Mood disorder QT prolongation	Liver function tests every 2 weeks for the first month of therapy then monthly Uric acid level at baseline and periodically CMP at baseline and periodically to anticipate risk of QT prolongation Ejection fraction at baseline and periodically	Also indicated for *NTRK* mutation positive NSCLC Can be taken without regard to meals
BRAF V600E Mutation				
Trametinib 2 mg (1 × 2 mg tablet) once daily	Edema Fatigue Fever Nausea/vomiting/diarrhea Rash	Cutaneous or other malignancy Hemorrhagic events Cardiomyopathy Colitis with or without perforation Hyperglycemia Interstitial lung disease Ocular toxicity Venous thromboembolism	Signs and symptoms of interstitial lung disease Fasting serum glucose at baseline and regularly Dermatologic evaluations at baseline and every 2 months Ejection fraction at baseline, 1 month after initiation of therapy then every 2-3 months Ophthalmic evaluation at baseline and within 24 hours of any visual disturbances	Should be used with dabrafenib Can be taken without regard to meals Permanently discontinue if symptomatic cardiomyopathy or decrease in ejection fraction by greater than 20% (0.20)
Dabrafenib 150 mg (2 × 75 mg capsules) twice daily	Edema Fatigue Fever Nausea/vomiting/diarrhea Rash	Cardiomyopathy Cutaneous or other malignancy Hemorrhagic events Hyperglycemia Uveitis	Fasting serum glucose at baseline and regularly Dermatologic evaluations at baseline and every 2 months Ejection fraction at baseline, 1 month after initiation of therapy then every 2-3 months	Should be used with trametinib Should be taken 1 hour before or 2 hours after meals Permanently discontinue if symptomatic cardiomyopathy or decrease in ejection

				fraction by greater than 20% (0.20) • Hemolytic anemia can occur if patient has glucose-6-phosphate dehydrogenase deficiency
MET exon 14 Mutation				
Capmatinib 400 mg (2 × 200 mg tablets) twice daily	• Edema • Decreased appetite • Dyspnea • Fatigue • Nausea/vomiting	• Hepatotoxicity • Interstitial lung disease • Photosensitivity	• Signs and symptoms of interstitial lung disease • Liver function tests at baseline then every 2 weeks for 3 months, then monthly	• Can be taken without regard to meals • Avoid coadministration of strong CYP3A inducers or inhibitors • Patients should be counseled regarding appropriate precautions to protect from ultraviolet light A/B exposure
Tepotinib 450 mg (2 × 225 mg tablets) once daily	• Dyspnea • Edema • Fatigue • Myalgias • Nausea/diarrhea	• Hepatoxicity • Interstitial lung disease	• Signs and symptoms of interstitial lung disease (dyspnea, cough, and fever) • Liver function tests at baseline then every 2 weeks for 3 months, then monthly	• Should be taken with meals
RET Rearrangement				
Selpercatinib 160 mg (2 × 80 mg capsules) twice daily	• Diarrhea • Edema • Fatigue • Hepatotoxicity • Hyperglycemia • Hypertension • Hypocalcemia • Leukopenia • Rash • Thrombocytopenia • Xerostomia	• Hemorrhage • Hypersensitivity • Impaired wound healing QT prolongation • Tumor lysis syndrome	• Liver function tests at baseline then every 2 weeks for 3 months, then monthly • Electrolytes, including calcium, at baseline and periodically • Blood pressure at baseline, 1 week after therapy initiation, then monthly • ECG at baseline and periodically	• Can be taken without regard to meals • Dose reduce to 120 mg if patient is less than 50 kg • Dose reduction recommended for severe hepatic impairment • Patients should watch for signs/symptoms of hypersensitivity • Hold therapy for planned surgical procedures

Pralsetinib 400 mg (4 × 100 mg capsules) once daily	• Constipation • Edema • Fatigue • Hepatotoxicity • Hypertension • Musculoskeletal pain • Myelosuppression	• Hemorrhage • Impaired wound healing • Interstitial lung disease • Tumor lysis syndrome	• Signs and symptoms of interstitial lung disease • Liver function tests at baseline then every 2 weeks for 3 months, then monthly • Blood pressure at baseline, 1 week after therapy initiation, then monthly	• Should be taken 1 hour before or 2 hours after meals • Dosing modifications required if used concomitantly with strong P-glycoprotein inhibitors or strong CYP3A inhibitors or inducers • Hold therapy for planned surgical procedures
NTRK Gene Fusion Positive				
Larotrectinib 100 mg (1 × 100 mg capsule) twice daily	• Constipation or diarrhea • Dizziness • Fatigue • Hepatotoxicity • Hypocalcemia • Musculoskeletal pain • Myelosuppression • Nausea/Vomiting	• CNS effects including cognitive impairment or mood disorders • Fractures	• Liver function tests at baseline then every 2 weeks for 1 month, then monthly	• Can be taken without regard to meals • Dosing modification required if used concomitantly with strong CYP3A4 inhibitors or inducers • Dose reduction recommended for patients with severe hepatic impairment • Inform patients to report signs/symptoms of possible fracture
KRAS G12C Mutation				
Sotorasib 960 mg (8 × 120 mg tablets) once daily	• Diarrhea • Fatigue • Hepatotoxicity • Musculoskeletal pain • Nausea	• Interstitial lung disease	• Signs and symptoms of interstitial lung disease • Liver function tests at baseline then every 3 weeks for 3 months, then monthly	• Can be taken without regard to meals • Avoid administration with drugs that decrease gastric acid • Has only been evaluated after progression on other therapies for advanced disease

Tumors should be tested for mutations in the kinase domain of EGFR (exon 18–exon 24). Deletion mutations in exon 19 and point mutations in exon 21 comprise 90% of EGFR mutations. The only mutation associated with resistance to EGFR inhibitors is an insertion mutation in exon 20, which results in steric hindrance that prevents the drug from binding to the kinase. The prevalence of EGFR mutations varies depending on tumor histology, ethnicity, sex, and smoking history. The highest prevalence occurs in adenocarcinomas, patients of Asian descent, biological females, and nonsmokers. The overall prevalence is 32% of NSCLC patients worldwide.[34]

Patients with a tumor that harbors an activating mutation in the EGFR receptor should receive a first-line EGFR kinase inhibitor.[5] In prospective randomized trials, first-generation EGFR inhibitors (erlotinib and gefitinib) provide superior progression-free survival compared with chemotherapy. Erlotinib has been evaluated in combination with recombinant monoclonal antibodies targeting VEGF. Erlotinib in combination with bevacizumab or ramucirumab has demonstrated improved progression free survival compared to erlotinib alone. However, this modest improved survival comes with more adverse drug reactions including hypertension and liver toxicities.[35,36] The second-generation inhibitor afatinib has also been shown to be better than chemotherapy as first-line therapy. Meta-analysis comparing EGFR inhibitors (erlotinib, gefitinib, and afatinib) suggests that these three agents have similar overall progression-free survival results (about 11 months) and response rates that are about two times higher than chemotherapy. The meta-analysis also showed that prognosis with exon 19 deletion is better than exon 21 L858R mutation.[37] Dacomitinib, another second-generation irreversible inhibitor, has been compared to gefitinib in this population. In a clinical trial, patients who were randomized to dacomitinib reported improved progression-free survival (14.7 vs 9.2 months) and overall survival (34.1 vs 26.8 months) compared with gefitinib.[38]

Osimertinib, a third-generation EGFR tyrosine kinase inhibitor, shows the most impressive activity in EGFR-positive tumors. The FLAURA trial evaluated patients with EGFR-positive NSCLC to receive first-line osimertinib or prescriber's choice of gefitinib or erlotinib. Patients receiving osimertinib had significantly longer median progression-free survival (18.9 vs 10.2 months) and median overall survival also favored osimertinib (38.6 vs 31.8 months).[39] Two other endpoints in this trial that favored osimertinib were the improved CNS response rate and lower rate of CNS disease defining progression, which is consistent with the improved CNS penetration of osimertinib. This finding is important for NSCLC patients because more than half will develop CNS metastasis during their disease course.[40] Osimertinib is also better tolerated than the first-generation agents, which is consistent with the lower affinity for wild-type EGFR. These characteristics make osimertinib the preferred agent to target EGFR-mutation positive tumors.[3]

Subsequent therapy after progression during treatment with an EGFR inhibitor depends on initial treatment and further genetic evaluation. Many clinicians will repeat tumor genetic testing to identify other targetable mutations before starting new therapy. If patients received initial therapy with a first- or second-generation agent, testing for the acquired T790M mutation should be conducted. If the tumor tests positive for T790M, osimertinib is the drug of choice. If the patient received initial therapy with osimertinib, systemic therapy is recommended.

Patients with exon 20 insertions tend to be resistant to treatment with EGFR kinase inhibitors. New treatment options have emerged for these patients. Amivantamab, is a bispecific antibody targeted to EGFR and MET. Overall response rate was 40% with a medium duration of response of 11.1 months in patients who progressed after platinum-based chemotherapy.[41] Mobocertinib is a kinase inhibitor administered orally that irreversibly binds and inhibits EGFR exon 20 insertion mutations at lower concentrations than wild type EGFR. This selective inhibition for mutant EGFR leads to a more favorable adverse drug reaction profile compared to other EGFR inhibitors.[42] It also is effective after platinum-based chemotherapy (overall response rate, 28% median duration of response, 17.5 months).[43]

In summary, patients with advanced NSCLC that harbors an EGFR mutation of exon 19 or L858R should be treated with first line osimertinib. Upon progression, patients can be retested for an additional targetable mutation/amplification. Most patients will proceed to a platinum doublet with or without immunotherapy. Patients with exon 20 insertions who have progressed on platinum-based chemotherapy should be treated with amivantamab or mobocertinib.

KRAS point mutations are another type of frequently occurring oncogenic mutation, occurring in 25% of patients with adenocarcinomas.[3] This mutation is more commonly associated with cigarette smoking and carriers a poor prognosis.[44] Since the discovery of this therapeutic target, finding an effective treatment for patients with KRAS mutations has been elusive. The KRAS inhibitor, sotorasib, is effective in patients with KRAS G12C mutated advanced NSCLC who were previously treated with standard therapies. Objective response was observed in 37.1% of patients and was durable (median duration of response, 11.1 months).[45]

The presence of an ALK rearrangement represents another therapeutic target for patients with NSCLC. The ALK mutation is less common than EGFR mutations, occurring in 2% to 5% of lung cancer patients.[46] Several ALK inhibitors have been approved for use. First-generation ALK inhibitors crizotinib and ceritinib established ALK inhibition as superior to chemotherapy. Each has shown improvement in median progression-free survival compared to chemotherapy (crizotinib: 10.9 vs 7 months; ceritinib 16.6 vs 8.1 months).[47,48] Second-generation inhibitors alectinib and brigatinib have higher activity than their first-generation counterparts and have demonstrated a dramatic improvement in outcomes compared with crizotinib therapy (median progression-free survival: alectinib, 34.8 vs 10.9 months and brigatinib, 24 vs 11 months).[49,50] The third-generation inhibitor lorlatinib has built on the success of its predecessors with improved potency and improved penetration of the blood-brain barrier. The CROWN trial demonstrated superiority of lorlatinib over crizotinib in a head-to-head comparison (median progression-free survival, not yet reached, [exceeding 33 months] vs 9.3 months).[51] It is important to note that of the second- and third-generation ALK inhibitors, only alectinib has shown improved overall survival compared to crizotinib.[48] Based on this evidence, patients with ALK-positive advanced NSCLC should receive initial treatment with a second (alectinib or brigatinib) or third (lorlatinib)–generation ALK inhibitor.[3]

Patients who relapse while receiving initial ALK-targeted therapy may be treated with an advanced-generation ALK inhibitor. Patients who initially received crizotinib can receive second- or third-generation inhibitors, while patients initially treated with a second-generation inhibitor should be offered lorlatinib. Lorlatinib is able to produce complete responses, even in patients with CNS disease.[52] Patients already receiving lorlatinib who have limited relapse can be treated with local therapy (such as radiation) and continuation of lorlatinib. Patients with widespread relapsed disease should be considered for the non-biomarker driven pathway.[3,5]

Mutation in ROS1 is a rare genetic driver of NSCLC occurring in 1% of patients. It has proven to be a highly active target for drug therapy. In patients with metastatic, ROS1-positive NSCLC, regardless of prior chemotherapy for metastatic disease, crizotinib has a 72% response rate, including a 6% complete response rate.[53] Certinib and entrecitinib produce similar responses (62% and 77%), but are better tolerated than crizotinib.[3] Additionally, entrecitinib has better CNS penetration than crizotinib. Similar to when used in patients with ALK mutations, lorlatinib produces response rate was 36%, including in patients with CNS disease.[52] Ceritinib, crizotinib, or entrecitinib are recommended first-line agents, with lorlatinib and entrecitinib as potential second-line therapy.

For the 1% to 2% of patients with metastatic adenocarcinoma who have the BRAF^{V600E} mutation, the combined use of trametinib, a mitogen-activated extracellular signal-regulated kinase, or MEK, inhibitor, and dabrafenib, an inhibitor of some mutated BRAF kinases, has been shown to be beneficial. The combination of trametinib and dabrafenib produces response rate of 63% to 64%, including complete responses in 6% of patients and median progression-free survival times of 9.7 to 10.9 months, in patients with or without prior chemotherapy.[54,55] This combination of kinase inhibitors is approved for the treatment of patients with metastatic BRAF^{V600E}-positive lung cancer, regardless of prior chemotherapy.[3]

Larotrectinib is a novel agent that is approved for the treatment of adult and pediatric patients with a metastatic solid tumor that is positive for a NTRK gene fusion. 0.2% of patients with NSCLC have this genetic driver of tumor growth. Larotrectinib's approval is based on a study of patients with a variety of solid tumors, including NSCLC.[56] Similarly, entrectinib may be used as a first-line treatment for patients with NTRK gene fusions, based on an accelerated approval of three ongoing phase 1 or 2 clinical trials of patients with advanced or metastatic NTRK fusion-positive solid tumors.[57]

Other less common mutations that occur in NSCLC that have specific targeted agents available include METex14 skipping mutation and RET fusions, both of which occur in about 1% to 2% of all NSCLC patients.[3] Capmatinib is a tyrosine kinase inhibitor that inhibits several MET mutations, including METex14 skipping mutation.[58] Tepotinib can also be used in patients with METex14 skipping mutations.[59] In patients with RET gene rearrangements, selective RET inhibitors, selpercatinib and pralsetinib can be used, resulting in positive response in patients who have progressed on chemotherapy and patients who are treatment naïve.[60,61]

After options targeting genetic mutations have been exhausted, other systemic therapies may be considered with most patients proceeding down the "nonbiomarker-driven" pathway.[3]

Chemotherapy for PD-L1+ and Nonbiomarker Tumors

Cytotoxic chemotherapy with a platinum-based doublet backbone is considered the standard of care for managing NSCLC without targetable genetic mutation. A variety of combinations have been evaluated, but the most used doublets consist of either cisplatin or carboplatin combined with paclitaxel (or nab-paclitaxel) or pemetrexed.[3,4] In general, carboplatin and paclitaxel have less toxicity for patients with squamous cell NSCLC.[62] For patients with nonsquamous NSCLC, a combination of a platinum agent with pemetrexed is widely considered the preferred chemotherapy regimen.

This was seen in a pivotal phase III trial of NSCLC patients compared six cycles of cisplatin and either gemcitabine or pemetrexed. When overall survival was analyzed by histology, cisplatin and pemetrexed was superior to other platinum combinations in patients with nonsquamous NSCLC. Furthermore, cisplatin and pemetrexed had less neutropenia, anemia, and thrombocytopenia but more nausea compared to other regimens.[63]

Maintenance therapy is the ongoing use of one or more agents after a positive tumor response to four to six cycles of an initial chemotherapy regimen until disease progression.[3] Several studies show that continuation or switch maintenance therapy improves survival of NSCLC patients with nonsquamous histology.[4] In continuation maintenance therapy, patients receive ongoing treatment with at least one of the agents used in the initial chemotherapy regimen. Alternatively, switch maintenance therapy starts a new agent not included in the initial regimen. Pemetrexed is the most established maintenance chemotherapy option. A meta-analysis showed that pemetrexed, given as maintenance therapy, provided a consistent overall survival benefit in patients with nonsquamous NSCLC.[64] A retrospective study reported improved progression-free and overall survival in patients who continued bevacizumab after completing initial chemotherapy with bevacizumab. A meta-analysis of trials of combined pemetrexed and bevacizumab maintenance therapy showed improved progression-free survival. However, no difference in overall survival was observed and the combination resulted in more toxicity.[65] Because of concerns about efficacy (pemetrexed) and safety (bevacizumab), maintenance with these agents is not recommended for patients with squamous NSCLC. Based on the benefit of maintenance therapy, trials of immunotherapy included maintenance therapy with the monoclonal antibody components of their regimens.

Novel agents such as checkpoint inhibitors and other targeted therapies are often being combined with platinum doublet chemotherapy. These regimens and their survival benefits are described later in this chapter.

PD-L1+ Tumors

⑧ Patients who have PD-L1+ tumors and no sensitizing mutations are eligible for a variety of first-line immunotherapies with checkpoint inhibitors. Food and Drug Administration approved checkpoint inhibitors for NSCLC include pembrolizumab, atezolizumab, nivolumab, and cemiplimab. These immune checkpoint inhibitors either bind to the PD1 receptor on T cells (pembrolizumab, nivolumab, cemiplimab) or the PD-1 ligand (PD-L1) on tumor cells (atezolizumab, durvalumab). Checkpoint inhibitors are associated with improved overall survival compared to patients receiving cytotoxic chemotherapy.[3] These agents may be used alone, in combination with chemotherapy, or a CTLA-4 inhibitor, ipilimumab. Certain patients may be contraindicated to treatment with checkpoint inhibitors. These include patients with a history of autoimmune diseases, on concomitant treatment with immunosuppressive agents, or those who harbor driver mutations. Presently, recommended treatments are guided by a patient's PD-L1 positivity status or TPS threshold. Patients are divided into three distinct categories: TPS ≥50%, TPS 1-49%, and TPS < 1%.

TPS ≥50% Treatment Recommendations

Regardless of histology, single-agent checkpoint inhibitor is recommended as initial treatment in patients with metastatic NSCLC with PD-L1 expression levels of at least 50%, and who are negative for sensitizing oncogenic mutations. This recommendation came from a pivotal phase III trial that showed both improved median progression-free (10.3 vs 6 months) and overall survival (30 vs 14.2 months).[66,67] In addition to pembrolizumab, atezolizumab and cemiplimab have significantly prolonged overall survival and improved tolerability compared to platinum chemotherapy in the first line setting for patients with metastatic PD-L1+ ≥50% NSCLC tumors.[3,68,69] All three agents are designated as preferred first-line therapies in this setting. The selection of which agent to use is often made by the ordering clinician.

Although patients with NSCLC who are PD-L1 of more than 50% benefit from immunotherapy monotherapy, a variety of other treatment strategies may be utilized to enhance clinical benefit or due to immunotherapy contraindications. Alternatives to immunotherapy monotherapy include chemoimmunotherapy, dual immunotherapy, or chemotherapy alone. These treatment modalities are described in more detail below.

TPS 1-49% Treatment Recommendations

Combination therapy that consists of a checkpoint inhibitor and chemotherapy is recommended as the preferred first-line treatment in patients with metastatic NSCLC, regardless of PD-L1 expression levels and histology. For adenocarcinoma NSCLC, combination therapy with pembrolizumab plus chemotherapy is preferred because it improves overall one-year survival rates (69.2% vs 49.4%).[70] Different treatment regimens are utilized for patients with a diagnosis of squamous NSCLC. For this histology, a combination of pembrolizumab plus carboplatin and either paclitaxel (or albumin-bound paclitaxel) is preferred as initial treatment regardless of PD-L1 expression levels because it improves overall survival (15.9 vs 11.3 months).[3,71] Refer to Table 152-4 for additional treatment options for patients with squamous NSCLC.

Since the approval of pembrolizumab in combination with chemotherapy, the management of both squamous and nonsquamous NSCLC has substantially changed. At the time of this writing, over seven first-line treatments are now being utilized. Therefore, management has shifted from a defined algorithm of platinum doublet chemotherapy into one where there are multiple competing first-line strategies. The advantages of this paradigm shift are that treatment regimens can be individualized to a patient's treatment goal, preferences, specific-factors, and/or performance status. One possible treatment strategy is to use a chemotherapy-free regimen of nivolumab and the cytotoxic T-cell lymphocyte associated protein 4, or CTLA-4, inhibitor, ipilimumab, which improves outcomes compared with chemotherapy alone in patients with metastatic NSCLC with a PD-L1 expression level of 1% or higher.[72] Dual immunotherapy is therefore an option for patients who are contraindicated to chemotherapy (eg, renal impairment.)[3] Another alternative treatment strategy is the concept of limited chemotherapy. The advantage of using a limited-chemotherapy strategy is that effective disease control and improved overall survival can be achieved without suppressing any immunogenicity.[73] This was demonstrated in a landmark phase III double-blind trial who received nivolumab/ipilimumab and two cycles of platinum-doublet chemotherapy followed by nivolumab/ipilimumab maintenance compared to four cycles of chemotherapy alone. Overall survival was improved with chemoimmunotherapy (nivolumab/ipilimumab) and two cycles of platinum-doublet chemotherapy followed by nivolumab/ipilimumab maintenance compared to four cycles of chemotherapy alone (15.8 months vs 11 months, respectively).[74] This treatment strategy may be ideal for a patient who requires a limited-chemotherapy option or is contraindicated to receiving ongoing chemotherapy maintenance.

Furthermore, single-agent immunotherapy with pembrolizumab may also be used. This recommendation was based from a randomized phase III trial comparing first-line pembrolizumab to chemotherapy in patients with NSCLC with a PD-L1 expression of 1% or more (TPS of ≥1%).[75] Patients with the highest level of PDL-1 expression (TPS ≥50%) had a median overall survival of 20 months versus 12 months in the chemotherapy arm, respectively. The survival benefit decreased as PD-L1 expression decreased, but survival was higher for the pembrolizumab in all groups. In certain circumstances, such as poor ECOG performance status or those who cannot tolerate or refuse platinum-based chemotherapy, single-agent checkpoint inhibitors may be used in patients who have expression levels of 1-49%. Other first-line treatment strategies may be utilized and can be seen in Table 152-4.

Nonbiomarker Driven

Approximately, half of the NSCLC patient population have TPS scores <1% or are PD-L1 negative.[76,77] Due to the lack of randomized clinical trials for this patient population, there are no defined or optimal treatment strategies that have been identified now. Therefore, patients who are PD-L1 <1%, a performance status of 0-2, and negative for actionable oncogenes are treated similarly to patients with TPS scores of 1% to 49% with pembrolizumab in combination with chemotherapy being the preferred initial treatment.[3]

For patients with metastatic NSCLC who are not candidates for targeted therapies or have progressed despite targeted therapies and are candidates for further therapy, combination chemotherapy in the form of a platinum doublet is the preferred treatment option. Targeted therapies have also been incorporated to various platinum doublet regimens. The benefit of adding the VEGF inhibitor, bevacizumab to a platinum doublet chemotherapy regimen leads to longer median progression-free survival (6.2 vs 4.5 months) and overall survival times (12.3 vs 10.3).[78] Therefore, the addition of bevacizumab to chemotherapy is recommended for patients with advanced NSCLC. However, due to the bleeding risk associated with bevacizumab, eligible patients must have nonsquamous histology, no recent hemoptysis, no CNS metastasis, and are not receiving therapeutic anticoagulation.[3] Cisplatin and pemetrexed have not been directly compared with carboplatin, paclitaxel, and bevacizumab and both regimens are listed as treatment options in nonsquamous NSCLC.

The most recent treatment advancement is using chemoimmunotherapy which was described earlier in this chapter. However, for patients with driver mutations, the use of chemoimmunotherapy is controversial. Patients with driver mutations like EGFR and ALK do not have the same responsiveness to immunotherapy compared to patients without driver mutations.[79] Furthermore, second-line trials have also demonstrated that these subsets of patients do not derive an overall survival benefit with checkpoint blockade.[80,81] When checkpoint inhibitors are combined with anti-angiogenic agents (eg, VEGF inhibitors), it is possible to overcome the tumor resistance seen in EGFR and ALK positive tumors. This may be due to VEGF inhibitors augmenting chemoimmunotherapy by suppressing antigen presentation and potentiating PD-L1 blockade.[81] This mechanism of action hypothesis was confirmed in the IMpower150 study which evaluated the addition of atezolizumab to treatment with carboplatin, pemetrexed, and bevacizumab (ABCP) in patients with nonsquamous NSCLC.[82] ABCP resulted in significantly longer median progression-free survival for all patients (8.3 vs 6.8 months) as well as those with EGFR or ALK mutations (9.7 vs 6.1 months). ABCP remains the first chemoimmunotherapy regimen to show a benefit in patients with driver mutations. Clinical guidelines recommend the combination of checkpoint inhibitors with a VEGF inhibitor, and chemotherapy as first-line therapy for patients with nonbiomarker-driven NSCLC.[3]

Relapsed Disease

Inevitably, patients with metastatic NSCLC will experience disease progression. For patients without driver mutations or patients who have exhausted available targeted therapies, systemic chemotherapy or immunotherapy remain the treatment of choice.

Monotherapy with nivolumab, pembrolizumab, atezolizumab, docetaxel, or pemetrexed are the most commonly considered options for second-line therapy in patients with a good performance status who progress during or after first-line chemotherapy.[3–5] Nivolumab and pembrolizumab, and atezolizumab, are options in the second-line setting for patients who have not previously received immunotherapy. A meta-analysis of randomized trials of PD-1 inhibitors found that these agents significantly improved survival outcomes as compared to single-agent chemotherapy.[83] This benefit was seen regardless of histology. Clinical benefit from PD-1 inhibitors is superior compared to docetaxel regardless of the level of PD-1 expression. However, patients with higher levels of PD-1 expression received an even greater benefit than those patients with low-level expression.

For patients who have failed initial treatment with immunotherapy, second-line treatment would be chemotherapy. Docetaxel was the first chemotherapy to receive Food and Drug Administration approval for the treatment of advanced NSCLC after failure of a platinum-based chemotherapy regimen. Docetaxel, at the 75 mg/m^2 dose, was superior to best supportive care in terms of time-to-disease progression (10.6 vs 6.7 weeks), median survival (7.5 vs 4.6 months), and 1-year survival (37% vs 11%).[84] The efficacy of docetaxel has been improved with the addition of ramucirumab. A large, randomized trial of docetaxel with or without ramucirumab reported longer progression-free survival (4.5 vs 3 months) and overall survival (10.5 vs 9.1 months) favoring the ramucirumab arm.[85] Response by histology was not analyzed, but ramucirumab appeared to be active in all histologies. Due to the relatively modest improvement in survival, clinicians must decide if the benefit outweighs the risks in adverse drug reactions and cost. Although ramucirumab binds to the VEGF receptor, it is important to note that safety concerns (serious and fatal bleeding) like those seen with bevacizumab and chemotherapy in squamous histology were not reported.

The second chemotherapy agent approved as second-line treatment is pemetrexed. When compared to docetaxel, there were no difference in efficacy outcomes but there were significantly fewer adverse drug reactions in patients receiving pemetrexed, including lower rates of hospitalizations due to toxicities[86] Pemetrexed is a preferred chemotherapy option based on this study, but it is not appropriate as second-line therapy when it is used as maintenance therapy. It is also important to note that pemetrexed should not be used for patients with squamous NSCLC.

The comparative trials indicate that pemetrexed and docetaxel are equally effective, and docetaxel plus ramucirumab is superior to docetaxel alone. Similarly, nivolumab, pembrolizumab, and atezolizumab are superior to docetaxel alone.[87] All five monotherapies and ramucirumab-docetaxel are acceptable regimens, but checkpoint inhibitors are preferred in patients who are naïve to this modality due to an impressive durability of response.[3] It is not clear, if a platinum doublet should be used or a single cytotoxic agent. If a platinum doublet is selected, then the regimen would be selected based on histology (as described below for tumors that are PD-L1 negative and have no targetable genetic mutations). If single-agent chemotherapy is selected, pemetrexed is preferred for non-squamous cell tumors and docetaxel with or without ramucirumab for squamous cell tumors (Table 152-4). However, since most patients with relapsed metastatic disease are heavily pretreated and are more likely to experience significant adverse drug reactions, single-agent chemotherapy tends to be preferred.

Third-line therapy (and beyond) is reasonable for patients who have a good performance status and can tolerate another agent. Monotherapy with an active agent would typically be used in this setting. For patients who received a PD-L1 guided therapy, docetaxel would be an option with or without ramucirumab. For those who received second-line docetaxel with or without ramucirumab, an immune checkpoint inhibitor would be an option. For patients who want treatment beyond third line, a single agent could be used.[3–5] The best agent(s) has not been determined in clinical trials. Therapeutic decisions are based on patient-specific factors including prior therapies and potential contraindications to specific agents. The most common treatment option is monotherapy with an agent known to have activity in clinical trials.

Older Patients and Poor-Performance Status

Single-agent chemotherapy is an alternative in older patients (>65 years old) or those with an ECOG performance status of 2 or greater. First-line, single-agent chemotherapy has objective response rates of 5% to 25% with no significant effect on overall survival. Rarely, complete responses occur and tend to have limited durations.[88] The most active cytotoxic chemotherapy agents are cisplatin, carboplatin, docetaxel, paclitaxel, etoposide, gemcitabine, ifosfamide, irinotecan, topotecan, mitomycin, vinblastine, vinorelbine, and pemetrexed.[3] Targeted therapies are also active as a single agent and should be considered in patients with a mutation-positive tumor.

Historically, patients with an ECOG performance status 2 were excluded from NSCLC trials because of excessive toxicity with minimal benefit from combination cytotoxic therapy. Updated ASCO guidelines state that available data support the use of single-agent and combination chemotherapy but are relatively weak and incorporate older patients or poor patients with a poor performance status. They emphasize the need to individualize this decision.[4,5] A recent meta-analysis shows that patients with performance status 2 benefit from treatment. The NCCN guidelines list both single agents and combinations for patients with a performance status of 2, and best supportive care for patients with a performance status of 3 or 4 unless they have a mutation or gene rearrangement where they can receive a tyrosine kinase inhibitor.[3]

Evaluation of Therapeutic Outcomes

For patients who have undergone surgical resection, a physical examination and chest radiography are recommended every 3 to 4 months for the first 2 years, then every 6 months for 3 years, and then annually. In addition, a low-dose spiral chest CT scan is recommended annually to monitor for evidence of local recurrence. Suspicious symptoms or physical findings (eg, bone pain, visual abnormalities, headache, or elevated liver function tests) should prompt an evaluation to rule out distant metastases.[3–5]

Tumor response to chemotherapy is generally evaluated at the end of the second or third cycle and at the end of every second cycle thereafter. Patients with stable disease, with an objective response, or with a measurable decrease in tumor size (complete or partial response) should continue until four to six cycles have been administered. Patients with nonsquamous histology tumors who respond (ie, nonprogressive disease) should be considered for maintenance therapy with pemetrexed. Following initial therapy for NSCLC, patients must be monitored for evidence of disease progression.[3–5] Second-line therapy and beyond is traditionally given until progression. The immune checkpoint inhibitors can display a different response pattern than traditional chemotherapy or targeted therapy. It can take some time for the immune system to become activated and then the tumor will initially be infiltrated with cytotoxic lymphocytes that can appear radiographically as progression prior to a response. The median time-to-response for immune checkpoint inhibitors is 10 to 12 weeks. Although the registry trials continue to assess response based on Response Evaluation Criteria in Solid Tumors (RECIST) criteria, an immune response criterion has been proposed where progression needs to be documented on two consecutive assessments at least 4 weeks apart.[89]

Small Cell Lung Cancer

Small cell lung cancer is a rapidly dividing malignancy that spreads early in the disease course. Consequently, about 60% to 70% of patients present with extensive-stage disease. When patients with SCLC are not treated, the disease quickly becomes fatal. Fortunately, SCLCs are responsive to chemotherapy and radiation. Chemotherapy with or without radiotherapy is the treatment of choice for most patients. Even after a complete response to therapy, the cancer usually recurs within 6 to 8 months, and survival time following recurrence is typically short (about 4 months). With treatment, median survival rates for patients with limited and extensive disease are 14 to 20 and 9 to 11 months, respectively. Treatment planning starts with stage of disease (ie, limited vs extensive stage), but must also consider other factors, including performance status (treatment usually restricted to performance status 0 or 1), patient age, comorbid conditions (eg, renal failure), and patient desire to receive treatment.[2,16]

Limited Disease

⑨ When a single SCLC mass is found, local therapy with radiation or surgery is considered, although the use of surgery in SCLC is limited to solitary nodules, without evidence of metastasis to lymph nodes. One of the differences between SCLC and NSCLC is that radiation is preferred for treatment of local disease over surgery. Radiation is always combined with chemotherapy in limited-stage SCLC, and the regimen of choice is etoposide and cisplatin (ie, EP regimen). Carboplatin may be substituted for cisplatin to reduce nausea and vomiting, nephrotoxicity, or neurotoxicity, although increased thrombocytopenia may result.[90] Alternative regimens have failed to demonstrate improved outcomes compared to EP plus concurrent radiation and typically have more toxicity. Guidelines recommend that the EP regimen be used with concurrent radiotherapy.[2,16] Regimens used in the treatment of SCLC can be found in Table 152-6. Because patients with SCLC commonly have a recurrence in the CNS, trials have been performed to evaluate the benefit of prophylactic cranial irradiation (PCI). A pivotal study showed that PCI reduces the incidence of brain metastasis and increases 3-year survival from 15% to 21%.[91] Therefore, patients who achieve a complete response with treatment should be offered PCI.

TABLE 152-6

Chemotherapy Regimens Used in the Treatment of SCLC

	Regimen	Drugs and Doses
First Line	Etoposide/cisplatin (EP)	Cisplatin 75 mg/m^2 IV on day 1 Etoposide 100 mg/m^2 IV on days 1-3; repeat cycle every 3 weeks for 4-6 cycles or Cisplatin 60 mg/m^2 IV on day 1 Etoposide 120 mg/m^2 IV on days 1-3; repeat cycle every 3 weeks for 4-6 cycles
	Etoposide/carboplatin (EC)	Carboplatin AUC 5-6 IV on day 1 Etoposide 100 mg/m^2 IV on days 1-3; repeat cycle every 3 weeks for 4-6 cycles
	EC + atezolizumab[a]	Carboplatin AUC 5 IV on day 1 Etoposide 100 mg/m IV on days 1-3 Atezolizumab 1,200 mg IV on day 1; repeat cycle every 3 weeks for 4 cycles followed by Atezolizumab 1,200 mg every 3 weeks or 1680mg every 4 weeks as maintenance
	EP + durvalumab [a]	Carboplatin AUC 5-6 IV on day 1 Etoposide 80-100 mg/m2 IV on days 1-3 Durvalumab 1,500 mg IV on day 1; repeat cycle every 3 weeks for 4 cycles followed by Durvalumab 1,500 mg every 4 weeks as maintenance
	EC + durvalumab [a]	Cisplatin 75-80 mg/m^2 IV on day 1 Etoposide 80-100 mg/m^2 IV on days 1-3 Durvalumab 1,500 mg IV on day 1; repeat cycle every 3 weeks for 4 cycles followed by Durvalumab 1,500 mg every 4 weeks as maintenance
Second Line	Topotecan	Topotecan 1.5 mg/m^2/day IV days 1-5; repeat every 3 weeks
	Lurbinectedin	Lurbinectedin 3.2 mg/m^2/day IV day 1; repeat every 3 weeks

[a] Extensive stage only.

Extensive Disease

Historically, platinum regimens have been the treatment of choice in extensive disease as studies have failed to show superiority to the EP regimen as first-line treatment. As in limited disease, carboplatin is an acceptable substitute for cisplatin in EP.

⑧ Programmed death inhibition with either atezolizumab or durvalumab when added to standard chemotherapy in patients with extensive stage SCLC has been shown to improve overall survival. The addition of atezolizumab to standard chemotherapy improved median progression free survival (2 vs 4.3 months) and overall survival (12.3 vs 10.3 months).[92] Durvalumab demonstrated similar benefit, improving median overall survival from 10.3 to 13 months.[93] The complete regimens used in the studies are shown in Table 152-6.

Concurrent radiotherapy is not used routinely in extensive disease. However, a randomized study of extensive-stage patients responding to chemotherapy comparing observation or PCI reported that PCI decreased the 1-year risk of brain metastasis (14.6% vs 40.4%), and prolonged 1-year survival (27.1% vs 13.3%).[94] A more recent Japanese study reported that PCI reduced the risk of brain metastases but did not improve overall survival. The results of these studies led to guideline revisions recommending PCI for patients with extensive disease responding to chemotherapy.[2,16]

Relapsed Disease

Patients with SCLC who relapse or progress after first-line chemotherapy have a median survival of 4 to 5 months. Unfortunately, recurrent disease is usually less sensitive to chemotherapy.

⑩ Treatment approach for patients who experience relapsed SCLC often depends on the length of time between completion of the initial chemotherapy regimen and relapse. If this interval is less than 3 months, the patient has refractory SCLC and is unlikely to respond to second-line therapy and should receive best supportive care or be enrolled in a clinical trial. For those with greater than a 3-month time interval between first-line chemotherapy and relapse, the expected response rate to treatment is about 20%, and second-line therapy should be considered.[2,16] Based on limited evidence, if the interval between completion of initial chemotherapy and relapse is 6 months or greater, retreating the patient with the initial chemotherapy regimen may be considered.[2] Topotecan (intravenous and oral) is approved as second-line therapy for SCLC and has been considered standard second line treatment of SCLC based on a trial that randomized patients to intravenous topotecan or to cyclophosphamide, doxorubicin, and vincristine (CAV) regimen.[95] The response rates, time-to-disease progression, and overall survival were not different between groups. The proportion of patients experiencing symptom improvement was higher in the topotecan arm. There were fewer dose reductions for topotecan (1% vs 11%) due to improved adverse drug reaction rates except for more anemia and thrombocytopenia from topotecan. Oral topotecan is similar in terms of dosing, toxicity, and effectiveness compared to intravenous topotecan.[96]

Lurbinectedin, an alkylating drug that binds guanine residues in deoxyribonucleic acid (DNA) inhibiting oncogenic transcription and causing apoptosis, is another effective second-line agent in relapsed SCLC and an alternative to topotecan.[97] In a single arm trial, it produced an overall response rate of 35.2% lasting a median of 5.3 months. Common adverse drug reactions include myelosuppression, fatigue, and elevations in serum creatinine and liver function tests. Other agents recommended in national guidelines include single-agent PD-L1 inhibitor, irinotecan, gemcitabine, paclitaxel, docetaxel, oral etoposide, temozolomide, and vinorelbine; CAV regimen; and participation in a clinical trial.[2,16]

Evaluation of Therapeutic Outcomes

The effectiveness of first-line therapy is evaluated after two to three cycles of treatment. If the patient achieves a complete or partial response, therapy is continued for four to six cycles of therapy. If the patient has evidence of progressive disease, therapy is discontinued or changed to a non–cross-resistant regimen. In the case of SCLC, responding patients benefit from the addition of PCI following initial therapy. After recovery from first-line therapy, follow-up visits should occur every 3 months for years 1, 2, and 3, then every 4 to 6 months for years 4 and 5, and then annually for patients with either a partial or complete response.[2,3]

Complications and Supportive Care

Patients with lung cancer frequently have numerous concurrent medical problems. Such problems may be related to invasion of the primary tumor and its metastases, paraneoplastic syndromes (see “Clinical Presentation” earlier), chemotherapy and radiotherapy toxicity, or concomitant disease states (eg, cardiac disease, renal dysfunction, chronic obstructive pulmonary disease, asthma, or diabetes). Depression is also common and sometimes persistent in patients with SCLC and NSCLC and should be treated. Identification, diagnosis, and treatment of the whole patient may improve the patient’s overall quality of life and tolerance to cancer treatments.

11 The chemotherapy regimens used in the management of lung cancer are intensive and are associated with a wide variety of toxic effects. Nausea and vomiting may be severe. Cisplatin-containing regimens require the use of aggressive acute and delayed antiemetic regimens containing agents, such as serotonin antagonists, dexamethasone, and neurokinin-1 receptor antagonist, and olanzapine.[98] Patients experiencing protracted nausea and vomiting may require intravenous hydration and nutritional support. Myelosuppression is often the dose-limiting toxicity associated with chemotherapy. Granulocytopenia places patients at high risk for serious infections. Other toxic effects associated with these chemotherapy regimens include mucositis, anemia, nephrotoxicity, peripheral neuropathies, and ototoxicity. In multiple phase II clinical trials, trilaciclib, a cyclin-dependent kinase 4/6 inhibitor, has demonstrated efficacy in in decreasing the incidence and severity of chemotherapy-induced myeylosuppression when administered prior to chemotherapy for extensive stage small cell lung cancer.[99] Its utility in other settings, or in comparison/combination with colony stimulating factors has not been established.

About 30% to 65% of advanced-stage NSCLC patients will develop bone metastases, which may lead to significant bone pain, pathologic fractures, spinal cord compression, and hypercalcemia. A large meta-analysis determined denosumab, a RANK-ligand inhibitor and zoledronic acid (bisophosphonate) decrease the incidence of skeletal related events such as fractures. Additionally, both agents have been shown to delay the onset of first event. The meta-analysis also found that denosumab has been shown to prolong overall survival compared to no treatment for bone metastases. Zoledronic acid was not determined to affect survival.[100]

Patients receiving radiation therapy may experience complications including severe esophagitis, fatigue, radiation pneumonitis, and cardiac toxicity. These toxicities are usually more common and severe when radiation is combined with chemotherapy. The patient's baseline performance status and the degree of pulmonary dysfunction (eg, chronic obstructive pulmonary disease from years of tobacco use) must be considered in decisions concerning radiation dosage and fractionation.

Patients who receive an immune checkpoint inhibitor can develop immune-related adverse events, which frequently include the gastrointestinal tract, skin, and pneumonitis. Holding therapy and intervening with steroids can blunt the progression of these toxicities. The other key point is that responses to immune checkpoint inhibitors can be delayed in onset.[101] A new response criterion has been developed for immunotherapies, which differs from RECIST criteria by requiring documentation of significant tumor grown on two occasions at least 4 weeks apart to be defined as progression.

Lung cancer patients frequently receive complex pharmacologic regimens that include chemotherapeutic agents, immune checkpoint inhibitors, antiemetics, antibiotics, analgesics, anticoagulants, bronchodilators, corticosteroids, anticonvulsants, and cardiovascular agents. Such regimens necessitate intensive therapeutic monitoring to avoid drug-related and radiotherapy-related toxic effects and to optimize therapeutic outcomes for individual patients.

CONCLUSION

Lung cancers remain the leading cause of cancer-related mortality in the United States. Early detection of lung cancer through appropriate screening methods, along with decreased use of tobacco products have helped lower lung cancer incidence and mortality. Advances in targeted therapies, such as inhibitors of the programmed death pathway and oral kinase inhibitors targeting specific mutations found in tumor cells, have had significant impact on the survival of patients with lung cancer.

ABBREVIATIONS

ALK	anaplastic lymphoma kinase
ASCO	American Society of Clinical Oncology
AUC	area under the curve
BRAF	B-rapidly accelerated fibrosarcoma

CAV	cyclophosphamide, doxorubicin, and vincristine
CBC	complete blood count
CMP	comprehensive medical panel
CNS	central nervous system
CPK	creatine phosphokinase
CT	computed tomography
DNA	deoxyribonucleic acid
EC	etoposide and carboplatin
ECG	electrocardiogram
ECOG	Eastern Cooperative Oncology Group
EGFR	epidermal growth factor receptor
EP	etoposide and cisplatin
ETS	environmental tobacco smoke
HER2	human epidermal growth factor
IP	irinotecan and cisplatin
KRAS	Kirsten rat sarcoma viral oncogene homologue
LDCT	low-dose computed tomography
MET	mesenchymal epithelial transition factor
MIA	minimally invasive adenocarcinoma
NCCN	National Comprehensive Cancer Network
NSCLC	non-small cell lung cancer
NTRK	neurotrophic receptor kinase
PCI	prophylactic cranial irradiation
PD-1	programmed death-1
PD-L1	programmed death ligand-1
PET	positron emission tomography

RECIST	response evaluation criteria in solid tumors
RET	rearranged during transfection
ROS1	receptor tyrosine kinase 1
SCLC	small cell lung cancer
TKI	tyrosine kinase inhibitor
TNM	tumor, node, and metastasis
TPS	tumor proportion score

SELF-ASSESSMENT QUESTIONS

1. A 59-year-old individual with recently diagnosed limited-stage small cell lung cancer comes to the clinic for treatment. Which of the following would be the most appropriate treatment?

    A. Cisplatin plus vinorelbine

    B. Surgery followed by adjuvant cisplatin plus etoposide

    C. Carboplatin, paclitaxel, and bevacizumab

    D. Cisplatin, and etoposide along with concurrent thoracic radiation therapy

2. Which of the following is the leading cause of cancer-related mortality in the United States?

    A. Breast cancer

    B. Prostate cancer

    C. Lung cancer

    D. Pancreatic cancer

3. A 68-year-old individual who quit smoking 18 years ago comes to the clinic asking, “Should I undergo screening for lung cancer?” Past medical history is significant for hypertension and chronic obstructive pulmonary disease. Social history is significant for a 31-pack year history of smoking and drinks a beer or two a day. What is the appropriate lung cancer screening recommendation for this patient?

   A. Lung cancer screening is not appropriate for this patient

   B. Annual chest x-ray

   C. Annual sputum cytology

   D. Annual helical CT scan

4. Which of the following is a leading risk factor for the development of lung cancer?

   A. Chronic obstructive pulmonary disease

   B. Asthma

   C. Cigarette smoking

   D. Carbon monoxide inhalation

5. Which subtype of lung cancer is the most commonly diagnosed?

   A. Non-small cell lung cancer

   B. Small cell lung cancer

   C. Mesothelioma

   D. Large cell carcinoma

6. Which of the following patients with lung cancer should be a treatment goal of cure?

   A. A patient with newly diagnosed stage II adenocarcinoma who is able to undergo surgery

   B. A patient with extensive stage small cell lung cancer

   C. A patient with newly diagnosed stage IV lung cancer that is positive for the NTRK mutation

   D. A patient with squamous cell carcinoma of the lung that has relapsed after initial treatment that included surgery followed by combination chemotherapy

   Use the following scenario to answer Questions 7-9

   TQ is a 63-year-old individual with a new diagnosis of metastatic large cell carcinoma of the lung. Complete pathologic review revealed the following profile: ALK negative, EGFR negative, BRAF^{V600E} negative, PD-L1 negative. The oncologist has recommended starting chemotherapy with carboplatin/pemetrexed.

7. Which of the following monoclonal antibodies could be added to TQ’s chemotherapy regimen to help improve efficacy?

   A. Necitumumab

   B. Cetuximab

   C. Nivolumab

D. Pembrolizumab

8. TQ continued prior treatment for 14 months with stable disease. Unfortunately, the lung cancer has now progressed and TQ is to begin a new lung cancer treatment. Which of the following would be most appropriate for now?

A. Cisplatin/gemcitabine

B. Docetaxel/ramucirumab

C. Carboplatin/paclitaxel

D. Paclitaxel/erlotinib

9. An 82-year-old individual with recently diagnosed adenocarcinoma of the lung is found to have stage IV disease (liver metastases). PD-L1 TPS is 17%. Targetable genetic mutations were not identified. At home, the patient is bedridden due to severe chronic obstructive pulmonary disease that requires home oxygen. Social history is significant for a 60-pack year history. Which of the following approaches would be most appropriate for this patient?

A. Best supportive care

B. Osimertinib

C. Carboplatin, pemetrexed, and pembrolizumab

D. Pembrolizumab

10. What is the best treatment option for a 49-year-old individual who is chemotherapy naïve and was recently diagnosed with extensive-stage small cell lung cancer?

A. Carboplatin, pemetrexed, plus pembrolizumab

B. Cisplatin plus gemcitabine

C. Carboplatin plus paclitaxel

D. Cisplatin, etoposide, plus durvalumab

Use the following scenario to answer Questions 11-13

SP is a 62-year-old individual with a recent diagnosis of stage IIB NSCLC, adenocarcinoma histology. Complete pathological evaluation showed ALK positive, EGFR negative, ROS1 negative, BRAF^{V600E} negative, and PD-L1 negative. A prior medical history includes hypertension, type 2 diabetes, peripheral neuropathy, and gastroesophageal reflux disease. SP underwent surgery and is ready to receive chemotherapy.

11. Which of the following therapies is most appropriate for SP now?

A. Cisplatin and vinorelbine

B. Carboplatin, pemetrexed, and bevacizumab

C. Alectinib

D. Pembrolizumab

12. Which of the problems in the patient's prior medical history is most likely to be worsened if the patient were to receive platinum-based chemotherapy?

A. Hypertension

B. Type 2 diabetes

C. Peripheral neuropathy

D. Gastroesophageal reflux disease

13. Two years after completing chemotherapy, SP presents to the primary care physician with new-onset cough with hemoptysis. The evaluation revealed the patient's lung cancer has relapsed, now with multiple tumors in the lung of origin as well as several suspicious tumors in the liver. The pathologic evaluation reveals the same genetic features as the original tumor. Which of the following is the most appropriate treatment for SP now?

    A. Docetaxel and ramucirumab

    B. Atezolizumab

    C. Alectinib

    D. Osimertinib

14. Which of the following patients with small cell lung cancer should receive prophylactic cranial irradiation?

    A. Patients with limited-stage SCLC who achieve a complete response to their initial therapy.

    B. Patients with extensive-stage SCLC who do not respond to their initial therapy.

    C. All patients with limited-stage SCLC.

    D. All patients with extensive-stage SCLC.

15. A 64-year-old individual with a performance status of 1 returns to clinic with relapsed small cell lung cancer (SCLC), new bone, and liver metastases. The previous chemotherapy of carboplatin and etoposide was completed 9 months ago, followed by a course of cranial irradiation. The patient has been in good health and reports no other medical problems and request further treatment if it is reasonable. Based on this information, which of the following treatments would be appropriate?

    A. Topotecan

    B. Carboplatin and etoposide

    C. Pembrolizumab

    D. Lurbinectidin

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** For limited-stage SCLC, the preferred chemotherapy regimen is cisplatin with etoposide. Thoracic radiation should be administered concurrently with chemotherapy to improve the likelihood of a complete response (see the "Limited Disease" section).

2. **C.** Lung cancer is the leading cause of cancer-related mortality for both men and women in the United States (see the "Introduction and Epidemiology" section).

3. **A.** The NLST showed that in patients aged 55 to 74 years with at least a 30-pack year smoking history, annual low-dose helical CT scan decreases lung cancer–related mortality by 20% compared to annual chest x-ray. The patients in this study had to be current smokers or active smokers within the last 15 years. Since the individual quit smoking 18 years ago, they do not meet the criteria (see the "Screening and Prevention" section).

4. **C.** Cigarette smoking is the leading risk factor for the development of lung cancer (see the "Etiology" section).

5. **A.** Non-small cell lung cancer is the most commonly diagnosed form of lung cancer. Within this subcategory, adenocarcinoma is the most commonly diagnosed (see the "Histologic Classification" section).

6. **A.** Early-stage lung cancer, such as stage II resectable adenocarcinoma should be treated with curative intent. Advanced lung cancers, including stage IV NSCLC and extensive stage NSCLC, along with cancers that have relapsed, should be treated with the intent of prolonging survival and improving quality of life (see the Desired Outcomes" section).

7. **D.** Pembrolizumab has been shown to improve the efficacy of combination chemotherapy in the treatment of metastatic, nonsquamous NSCLC, regardless of PD-L1 expression. It has specifically been studied in combination with carboplatin and pemetrexed (see the "Nonbiomarker Driven" section).

8. **B.** Recurrent/relapsed NSCLC that is negative for all biomarkers (EGFR, ALK, BRAF^{V600E}) is most often treated with single-agent chemotherapy, such as docetaxel. Clinical trial evidence has shown that the addition of ramucirumab to docetaxel in this setting improved median overall survival. Ramucirumab may be used in all types of NSCLC (see the"Relapsed Disease section).

9. **A.** The patient has a performance status of 4 due to severe COPD. Treatment of NSCLC in patients with a poor performance status (PS) has not been shown to improve survival. The Eastern Cooperative Oncology Group (ECOG) PS delineation ranges from fully active to confinement to bed. Generally, patients with a status of 4 are typically not offered treatment, rather are managed with best supportive care (see the "PD-L1+ Tumors" section).

10. **D.** For extensive-stage SCLC to maximize survival, one should utilize cisplatin plus etoposide regimen. The addition of atezolizumab or durvalumab improves outcomes over chemotherapy alone (see the "Extensive Disease" section).

11. **A.** The patient is due to start adjuvant chemotherapy for the treatment of early-stage nonsquamous NSCLC. The combination of cisplatin and vinorelbine is one of the combination regimens recommended in this setting. (see the "Local Disease" section).

12. **C.** Cisplatin and carboplatin are both associated with neuropathy. In patients with preexisting neuropathy, platinum-based therapy can worsen their symptoms (see the "Complications and Supportive Care" section.)

13. **C.** The patient is positive for ALK. Since the initial regimen was used in the adjuvant setting for the treatment of early-stage lung cancer, chemotherapy was initially used. Now, in the relapsed setting, targeted therapy is preferred when possible. Since the patient is positive for ALK, therapy targeting this kinase can be used. Alectinib has demonstrated superior progression-free survival when compared to crizotinib, the first-generation ALK inhibitor (see the"Targetable Genetic Mutation" section).

14. **A.** Whether limited or extensive stage, patients with SCLC who achieve a complete response to their chemotherapy regimen should receive prophylactic cranial irradiation (PCI). In this situation, PCI decreases the incidence of brain metastases and improves overall survival (see the "Limited Disease" section).

15. **B.** The patient experienced relapse 9 months after completing the initial chemotherapy. Clinical practice guidelines recommend retreatment with the original regimen in patients with SCLC who achieve complete remission of 6 months or longer. Retreatment with carboplatin and etoposide is appropriate ("Relapsed Disease" section).

Chapter 153: Colorectal Cancer

Lisa M. Holle; Jessica M. Clement; Lisa E. Davis

KEY CONCEPTS

KEY CONCEPTS

① Advancing age, high-risk adenomatous polyps, inherited and acquired genetic susceptibilities, inflammatory bowel disease, diabetes mellitus, and lifestyle factors are associated with colorectal cancer risk.

② Regular use of aspirin and other nonsteroidal anti-inflammatory drugs reduces the risk of colorectal cancer, but it is not recommended for routine cancer prevention, nor are any other therapies.

③ Effective colorectal cancer detection programs incorporate routine screening starting at the age of 45 years for average-risk individuals. Colorectal adenomas can progress to cancer and should be removed.

④ The treatment goal for stages I, II, and III colon cancer is cure; surgery should be offered to all eligible patients. Six months of fluoropyrimidine-based adjuvant systemic therapy reduces the risk of cancer recurrence and overall mortality in patients with stage III and select patients with stage II colon cancer; 3 months may be considered in select patients with stage II and III colon cancer. An oxaliplatin-containing regimen further reduces risk as compared with fluoropyrimidine alone in stage III patients.

⑤ Adverse drug reactions with the most common drugs used in the treatment of colorectal cancer include fluorouracil/capecitabine: palmar-plantar erythrodysesthesia, stomatitis, diarrhea, leukopenia; oxaliplatin: acute and persistent peripheral neuropathies; irinotecan: diarrhea, neutropenia. Deficiencies in dihydropyrmidine dehydrogenase (DPD) and uridine diphosphate-glucuronosyltransferase (UGT1A1) may increase adverse drug reactions with fluorouracil/capecitabine and irinotecan, respectively.

⑥ Combined modality neoadjuvant therapy consists of fluoropyrimidine-based chemosensitized radiation therapy (XRT) and surgery for patients with stage II or III cancer of the rectum and is considered the standard of care to decrease risk of local and distant disease recurrence.

⑦ Chemotherapy is palliative for metastatic disease. A fluoropyrimidine with oxaliplatin or irinotecan improves survival compared to fluoropyrimidine monotherapy and should be offered to patients who are candidates for aggressive treatment. The ability for patients to receive all active cytotoxic agents (eg, fluoropyrimidine, oxaliplatin, and irinotecan) during the course of their disease improves their overall survival.

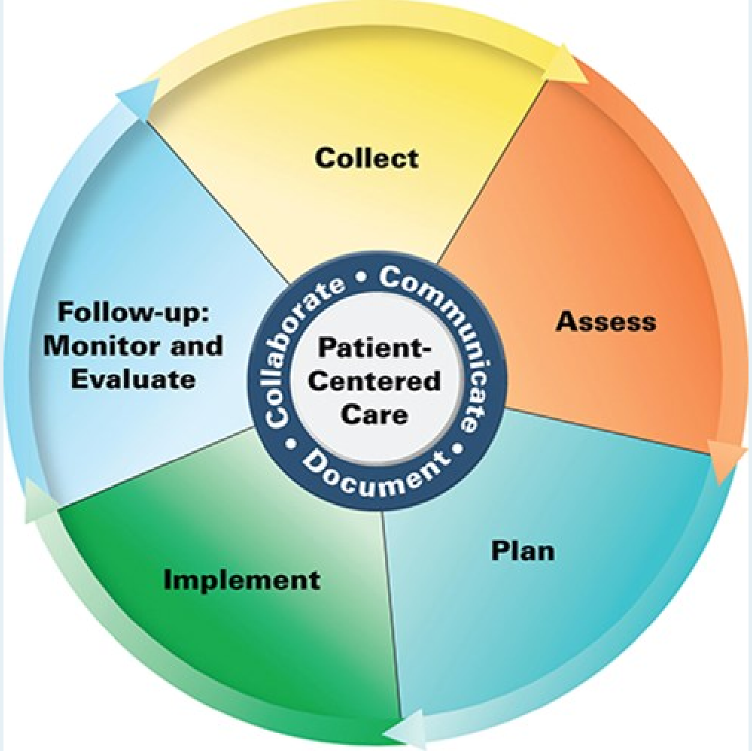
⑧ Bevacizumab plus fluoropyrimidine-based chemotherapy as initial therapy for metastatic disease is considered standard of care and provides a survival benefit compared with combination chemotherapy alone. Hypertension, proteinuria, and impaired wound healing are common adverse drug reactions.

⑨ The addition of an epidermal growth factor receptor (EGFR) inhibitor (cetuximab or panitumumab) to initial treatment for *RAS* and *BRAF* wild-type, left-sided advanced or metastatic disease may improve tumor response rates (RRs) and survival. Papulopostular skin rashes, diarrhea, and hypomagnesemia are common, and infusion-related reactions may also occur.

⑩ Immune checkpoint inhibitors can provide benefit to patients with metastatic colorectal cancer when a deficiency in DNA mismatch-repair (MMR) genes or high microsatellite instability (MSI) is present. These agents are associated with immune-mediated adverse drug reactions.

PATIENT CARE PROCESS

Patient Care Process for Colorectal Cancer



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, race, sex)
- Patient history (lifestyle factors—alcohol use, tobacco use, physical activity)
- Patient characteristics (eg, social history/situation, insurance coverage) and treatment preferences
- Patient medical and family history (eg, performance status, concurrent disease states [inflammatory bowel disease, colorectal cancer, polyps])
- Clinical presentation signs and symptoms (see Clinical Presentation Box)
- Current signs and symptoms and evaluation of tumor growth (for follow-up visits)
- Current medications (prescription, over-the-counter, and complementary alternative)
- Objective data
  - BP, heart rate (HR), height, weight, and BSA
  - Labs (eg, serum electrolytes, renal function, liver chemistries, complete blood count, coagulation studies, carcinoembryonic antigen [CEA] level—see Workup)
  - Physical examination data (eg, hepatomegaly, lymphadenopathy, ascites)
  - Colorectal cancer staging (see Table 153-4)
  - Colorectal tumor genomics (eg, *KRAS*, *NRAS*, MMR/MSI, *BRAF, PIK3CA, NTRK*)

Assess

- Risk factors for treatment-related toxicities (eg, *UGT1A1*28* genotype, DPD, poor nutritional intake, uncontrolled blood pressure or hypertension, baseline peripheral neuropathy)

- Type of and response to prior treatments
- Potential for disease responsiveness to specific agents and risk factors for disease recurrence
- Potential problems with medication adherence to oral treatment regimens
- Need for drug dose reductions or supportive care

Plan*

- Goals of treatment
- Drug therapy regimen including specific anticancer agent(s), dose, route, frequency, and duration (see Tables 153-5, 153-6, and 153-7)
- Supportive care plan (eg, antiemetics, prophylactic antidiarrheals, infusion reaction prophylaxis)
- Monitoring parameters including efficacy (eg, cancer imaging studies-chest, abdominal, and/or pelvic CT scans and radiographs, CEA if previously elevated, symptoms of recurrence), safety (medication-specific adverse drug reactions, including major-dose limiting toxicities), and time frame (see Tables 153-5, 153-6, and 153-7)
- Patient education (eg, goals of treatment, expected and potential serious toxicities, drug therapy, monitoring and management plan)

Implement*

- Provide patient education regarding all elements of treatment plan
- Survivorship care plan (eg, primary prevention of other diseases, such as infections, and other cancers; support systems for maintaining healthy lifestyle choices and BMI)

Follow-Up: Monitor and Evaluate

- Determine disease response to treatment (see "Evaluation of Therapeutic Outcomes" section) and occurrence of disease progression or recurrence (cancer imaging studies, CEA if previously elevated)
- Presence of adverse drug reactions (see "Evaluation of Therapeutic Outcomes" section and Tables 153-5, 153-6, and 157-7)
- Patient adherence to treatment plan using multiple sources of information (eg, patient self-report, medication administration records or refill data)
- Patient's satisfaction with treatment, including understanding of adherence

Collaborate with patient, caregivers, and other healthcare professionals.

BEYOND THE BOOK

BEYOND THE BOOK

For each of the available antiangiogenic inhibitor and EGFR inhibitors, describe when in the treatment of colorectal cancer (ie, neoadjuvant, adjuvant, first-line metastatic, second- or greater-line metastatic treatment) it is appropriate to use the drug, including the rationale and whether the drugs within a class are interchangeable. This activity is useful to enhance student understanding of the ASSESS, PLAN, and FOLLOW-UP steps in the patient care process.

INTRODUCTION

Colorectal cancer involves the colon, rectum, and anal canal. It is one of the three most common cancers in adult men and women in the United States.[1] In 2021, an estimated 149,500 new cases were diagnosed, of which 104,270 involves the colon and 45,230 involves the rectum. An additional 9,090 new cases of cancer involve the anus, anal canal, or anorectum. For both adult men and women, colorectal cancer is the third leading cause of cancer-related death in the United States. An estimated 52,980 deaths from cancer of the colon or rectum occurred during 2021.

Colorectal cancer mortality and incidence rates in the United States have decreased steadily over the past two decades. Incidence rates vary worldwide, with the highest incidence rates in countries with a high human development index (HDI).[2] The decline in colorectal cancer mortality rates is likely due to increased screening and/or improved treatments, but mortality rates continue to increase in low-income and middle-income countries in eastern Europe, Asia, and South America.

Multiple factors are associated with the development of colorectal cancer, including inherited susceptibility, lifestyle factors, and certain disease states. About 73% of affected individuals are diagnosed at an early stage of disease, which can potentially be cured with surgery alone or surgery followed by adjuvant XRT, chemotherapy, or both.[3] Five-year survival rates are about 91% for persons with early stages of colon and rectal cancer. Once the tumor has spread regionally to adjacent lymph nodes or tissues, the 5-year survival rate drops to 72% for both colon and rectal cancer. Five-year survival for individuals with metastatic disease is about 15%.

Treatment modalities for colorectal cancer include surgery, XRT, chemotherapy, targeted molecular therapies (eg, angiogenesis inhibitors and EGFR inhibitors), and immune checkpoint inhibitors. Surgery is the definitive procedure associated with cure. XRT can improve curability following surgical resection in rectal cancer and can reduce symptoms and complications associated with advanced disease. Chemotherapy is used in the adjuvant setting to increase cure rates and in treatment for advanced stages of disease to prolong survival. Some patients with metastatic disease who receive aggressive preoperative chemotherapy and targeted therapies experience higher resection rates and can be potentially cured. Much progress has been made in the treatment of advanced disease and the availability of active drug regimens that improve patients' survival.

EPIDEMIOLOGY

Colorectal cancer is the third most common diagnosed malignancy worldwide and the fourth most common cause of cancer-related deaths, accounting for about 1.9 million new cases and 935,000 deaths annually.[2] Although the highest incidence and mortality rates are found in economically developed countries, such as the United States, Australia, New Zealand, and Western Europe, where the HDI is highest, rates have stabilized or are decreasing. This is in contrast to countries with a medium-to-high HDI, such as Eastern Europe, Asia, and South America, where colorectal cancer incidence and mortality rates are increasing rapidly. These increases are believed to be associated with an increased prevalence of risk factors associated with westernization, such as unhealthy diet, obesity, and smoking. The lowest incidence rates are observed in less-developed areas such as sub-Saharan Africa and South Central Asia.

The incidence of invasive colon cancer is greatest among men, who have an age-adjusted incidence rate of 29.1 per 100,000, as compared with women for whom the rate is 24.3 per 100,000.[3] Invasive cancer of the rectum occurs less frequently, with an incidence rate of 14.1 and 9.0 per 100,000 for men and women, respectively. Differences in colorectal cancer incidence exist among ethnic groups in the United States, where incidence is highest among non-Hispanic Black individuals followed by American Indian/Alaska Native individuals, non-Hispanic White individuals, Hispanic individuals, and Asian/Pacific Islander individuals. Cultural and genetic factors as well as disparities in access to healthcare services may influence risk among population groups.

The overall incidence of colon and rectal cancers in the United States has steadily decreased since the mid-1980s, with an annual decline by 3.7% among individuals aged 65 years and older from 2009 to 2018.[3] However, the incidence rate increased by 1% per year in adults between 50 and 64 years of age and in adults younger than 50, the incidence of colorectal cancer increased by 2.2% annually. The incidence of colorectal cancer in adults younger than 55 has been increasing since the mid-1990s, with the most rapid increase in metastatic disease.[4]

Cancer incidence rates have been declining among every broadly defined racial/ethnic group since the mid-1990s, except in American Indian/Alaska Natives, for whom cancer incidence rates remain stable.[3]

Cancer of the colon and rectum accounts for about 8% of all cancer deaths in the United States.[1] The median age for death from cancer of the colon or rectum is 72 years. An estimated 52,980 individuals died of colorectal cancer in the United States in 2021, which represents a continued decline in overall combined mortality for both colon and rectal cancer. Overall mortality rates are highest among non-Hispanic Black individuals, although a steep rate of decline began in the late 1990s.[3] Colorectal cancer death rates are decreasing among all ethnic groups, but mortality rates are not lower in American Indian/Alaska Native individuals. Factors contributing to the overall decline in colorectal cancer mortality include decreasing incidence rates, screening programs with early polyp removal, and more effective and better tolerated treatments. Differences among different world geographic regions, and in population groups in the United States, may also reflect more unfavorable tumor characteristics, late stage at diagnosis, decreased access to screening programs, comorbidities, and lower availability or utilization of effective treatments.

ETIOLOGY AND RISK FACTORS

The development of colorectal cancer is related to both uncontrollable and modifiable risk factors. Age, family history, and clinical and genetic susceptibilities cannot be controlled by individuals. Modifiable lifestyle factors are responsible for more than half of the colorectal cancers.[4,5]

Personal Medical History

Age

① An individual's risk of developing cancer of the colon or rectum increases with advancing age, rising progressively after age 50.[4] The median age at colon cancer diagnosis is 67 years in men and 71 years in women and 62 years in men and 63 years in women for rectal cancer. The proportion of individuals diagnosed with colorectal cancer who were younger than 50 increased from 6% to 11% between 1990 and 2013, with the majority of cases diagnosed in adults in their 40s.[3] The increase in colorectal cancer incidence in younger adults may reflect trends in obesity and detrimental lifestyle factors, but the role of modifiable and non-modifiable risk factors in early-onset colorectal cancer remains unclear.

Adenomatous Polyps or Colorectal Cancer

A prior history of high-risk adenomatous polyps, particularly multiple adenomas or size 1 to 2 cm or more, is associated with an increased risk of colorectal cancer.[4,5] Individuals with a prior diagnosis of colon or rectal cancer have a greater risk of developing a new malignancy at another area in their colon or rectum as compared to individuals without a prior history of colorectal cancer.

Inflammatory Bowel Disease

Individuals with chronic inflammatory bowel disease, such as ulcerative colitis or Crohn's disease, have about a twofold greater risk of developing colorectal cancer than the average individual.[4-6] This risk rises with increasing extent, duration, and severity of disease, a familial history of colorectal cancer, and coexistent primary sclerosing cholangitis. Persons diagnosed with chronic inflammatory bowel disease constitute about 1% to 2% of all new cases of colorectal cancer each year.

Diabetes Mellitus

Individuals with type 2 diabetes mellitus have an increased risk of developing colorectal cancer, independent of body mass size and physical activity level. Epidemiologic studies show that diabetes is associated with 26% to 53% increase in risk of colorectal cancer, as well as a higher risk of colorectal cancer-related and all-cause mortality.[7] Metformin use may improve survival outcomes in patients with colorectal cancer and diabetes, but further study is needed.

Family History and Inherited Genetic Risk

Colorectal Cancer or Adenomatous Polyps

Three specific patterns of colon cancer occurrence are generally observed: sporadic, familial, and recognized hereditary syndromes. Although most cases of colorectal cancer are sporadic in nature, about 30% of patients who develop colorectal cancer will have a family history of colorectal cancer that is not associated with an inherited syndrome.[4,5] First-degree relatives of patients diagnosed with colorectal cancer have an increased risk of the disease (two times the risk), which is higher if the relative was diagnosed at age 45 or younger (three to six times higher). Similarly, parents and siblings of relatives diagnosed with adenomatous polyps are at increased risk for developing colorectal cancer.

Hereditary Syndromes

Colorectal cancer is a consequence of several well-defined genetic syndromes.[4,5] The two most common forms of hereditary colon cancer are familial adenomatous polyposis (FAP) and Lynch syndrome, historically known as *hereditary nonpolyposis colorectal cancer* (HNPCC). Both forms result from a specific germline mutation. FAP is a rare autosomal dominant trait caused by inactivating mutations of the adenomatous polyposis coli (*APC*) gene and accounts for about 1% of all colorectal cancers. The disease is manifested by hundreds to thousands of tiny sessile adenomatous polyps that carpet the colon and rectum, typically arising during adolescence. The polyps continue to proliferate throughout the colon, with eventual transformation to malignancy. The risk of developing colorectal cancer for individuals with untreated FAP is virtually 100%; most will develop colorectal cancer by the fourth and fifth decades of life.

Lynch syndrome is an autosomal dominant inherited syndrome and is the most common hereditary predisposition for colorectal cancer.[4,5] Patients with Lynch syndrome are predisposed to many types of cancer (eg, endometrial, stomach, and ovarian), but the risk of colorectal cancer is the highest.[4] Germline mutations in one of the DNA mismatch-repair (MMR) genes, most commonly *MLH1*, *MSH2*, *MSH6*, or *PMS2*, or rarely, epithelial cell adhesion molecule *(EpCAM)*, are responsible for Lynch syndrome, which accounts for 3% to 5% of overall colorectal cancer cases.[4,8] The estimated lifetime risk of developing colorectal cancer for carriers of germline MMR mutations is about 13% to 57%, depending on the specific affected gene.[8] Multiple generations within a family are affected, and colorectal cancer develops early in life, with a mean age at time of diagnosis of about 44 to 61 years.[5] If Lynch syndrome is suspected in a patient diagnosed with colorectal cancer, typically due to early age at diagnosis or family cancer history, the tumor is examined for evidence of deficient MMR to distinguish between sporadic or germline genetic mutations. Identify carriers of these MMR mutations so that they can be counseled and followed appropriately.[4,8]

Lifestyle Factors

Nonsteroidal Anti-inflammatory Drug and Aspirin Use

② Several lifestyle factors influence colorectal cancer risk (Table 153-1). Regular (at least two doses/week) nonsteroidal anti-inflammatory drug (NSAID) and aspirin use is associated with a reduced risk of colorectal cancer. In an average-risk individual, regular aspirin use is associated with a 20% to 40% reduction in the risk of colorectal adenoma and colorectal cancer.[9]

TABLE 153-1

Lifestyle Factors Associated with Colorectal Cancer Risk

Factor	Comments
Elevated Risk	
Physical inactivity	Sedentary lifestyle associated with a 25%-50% increased risk of colorectal cancer compared with the risk in physically active individuals
Obesity	Elevated BMI, waist circumference, and waist-to-hip ratio directly associated with increased cancer risk
Alcohol intake	Moderate and heavy alcohol consumption associated with 20% or greater cancer risk compared to light drinking (<1 drink/day)
Smoking	Prolonged tobacco smoking increases risk of large adenomas and carcinoma; higher colorectal cancer mortality in current smokers; risk persists after smoking cessation
Western diet	High red meat, processed meat, and saturated fat dietary consumption increases cancer risk; cancer risk lower with diets high in whole fiber grains and cereals, fruits, and vegetables
Reduced Risk	
Aspirin and non-aspirin NSAID use	Regular aspirin or NSAID use associated with 20%-45% reduction in adenoma recurrence and colorectal cancer risk. Benefit in risk reduction may require at least 5-10 years of use
Postmenopausal hormone use	Exogenous hormone intake decreases the risk of adenomas, colon, and rectal cancer by about 35%
Calcium and vitamin D intake	Vitamin D 400 international units and calcium intake of 1,000 mg/day (adults <50 years) or 1,200 mg/day (adults >50 years) may help reduce colorectal cancer risk but data remain unclear

BMI, body mass index.

Benefit is also seen with NSAID and cyclooxygenase-2 inhibitor (COX-2) use. NSAID use over a 10- to 15-year period is associated with protection against adenomas and colorectal cancer, with a 30% to 45% reduction in the risk of colorectal cancer.[9] The protective effects of these agents are related to their inhibition of COX-2, which is overexpressed and elevated in up to 50% of colorectal adenomas and 85% of sporadic colon carcinomas.[10] Inhibition of COX-2 also downregulates the phosphatidylinositol 3-kinase (PI3K) signaling pathway, which plays an important role in carcinogenesis and cancer cell resistance to apoptosis.[11]

Postmenopausal Hormone Replacement Therapy

Exogenous postmenopausal oral hormone replacement therapy is associated with a significant reduction in colorectal cancer risk.[9,12] Risk reduction is seen in postmenopausal individuals receiving combined estrogen and progestin therapy and persists for about 10 years after therapy is discontinued. However, because of the harmful risks associated with postmenopausal hormone replacement therapy, its use is not recommended to prevent colorectal cancer.

Obesity and Physical Inactivity

① Physical inactivity and elevated BMI are associated with an elevated risk of colon adenoma, colon cancer, and rectal cancer.[4,5,9] Compared to physically active individuals, physically inactive people have up to a 50% higher risk of developing colorectal cancer.[5]

Elevated BMI and higher general and abdominal body fatness are risk factors for colorectal cancer in adults, although the associations are weaker and less consistent for women.[4] The risk of colon cancer is about 50% higher in obese men, who also have a 25% higher risk of rectal cancer as compared to men of normal body weight. Obese women have about 10% increased risk of colon cancer, and even a higher body weight within the normal range appears to be associated with an increased risk of early onset colorectal cancer.

The relationship between physical inactivity and cancer risk is incompletely understood, but may be related to oxidative stress and immune dysfunction.[13] Obesity promotes insulin resistance, chronic inflammation, elevated insulin-like growth factor-1 levels, and altered levels of circulating sex hormones, which can contribute to tumorigenesis.[5,13]

Alcohol and Tobacco Use

① Moderate and heavy alcohol consumption is a major risk factor for colorectal adenomas and colorectal cancer.[4,5,14] Individuals with an intake of two to three alcoholic beverages per day have a 21% higher risk of developing colorectal cancer, and heavier drinking further increases cancer risk.[4,14] This association is stronger in men than in women, perhaps due to differences in drinking patterns or alcohol metabolism.

An estimated 12% of colorectal cancer deaths are attributed to cigarette smoking.[4,5] Cigarette smoking is associated with an increased risk of colorectal cancer (about 38% and 18% in current and former smokers, respectively) and mortality than in nonsmokers.[15] The risk of colorectal cancer development increases with longer duration of smoking and number of cigarettes consumed daily, and persists after smoking cessation.

Gut Microbiota

The gut microbiota could play an important role in the development of colorectal adenomas and adenoma progression to colorectal cancer.[4,5] The gut microbiome is involved in absorption and metabolism of nutrients, drug metabolism, elimination of xenobiotics, and immune cell function.[5] Certain bacterial species, such as *Fusobacterium nucleatum* and *Bacteroides fragilis*, produce bacterial metabolites that promote and sustain local inflammation, cause DNA damage, alter the immune response, and affect pro-tumorigenic cell signaling pathways.[16] Factors that alter the composition and function of normal gut microbiota, such as diet, lifestyle, obesity, and drug therapy (eg, antimicrobials, antacids, and proton pump inhibitors), may be associated with increased risk of colorectal cancer.

Dietary Intake and Nutrients

① Epidemiologic studies of worldwide incidence of colorectal cancer suggest economic development and dietary habits strongly influence its development. Dietary characteristics of economically developed countries and increased colorectal cancer risk include higher intake of red and processed meat, fat, and refined grains, and a lower intake of fruit, vegetables, and whole grains.

Many large epidemiologic studies have identified a positive association of a high consumption of red and processed meat with the risk of developing colorectal cancer.[4,5] Potential underlying mechanisms for this association include carcinogenic chemicals formed during the cooking process or the presence of specific fatty acids in red meat.[5] Processed meat products may increase exposure to carcinogenic nitrates and *N*-nitroso compounds.[5]

Worldwide, high-fiber dietary patterns have been associated with a low incidence of colorectal cancer.[2,5,9] Foods that are high in fiber include fruit, vegetables, whole grains, and cereals. Fruit and vegetables are rich in soluble fiber, vitamins, minerals, flavonoids, and other micronutrients that may be protective for colorectal cancer risk. However, the role of dietary fiber with regard to amount, source, and type and colorectal cancer risk has not been defined.

Dietary and supplemental calcium consumption is associated with a decreased risk of adenomas and colorectal cancer.[2,4,5,17] The protective effects of calcium may be due to antiproliferative, proapoptotic actions, and reduced colonic epithelial cell exposure to mutagens.[5,9] High levels of circulating 25-hydroxyvitamin D_3 are also associated with a reduced risk of colorectal cancer.[4,5,18] Vitamin D has antiproliferative, anti-inflammatory, and immune regulatory effects.[5,9,18] Vitamin D and calcium appear to interact synergistically to protect against adenoma recurrence and colorectal cancer, but large clinical trials have yet to confirm that supplementation with calcium and vitamin D in individuals with adequate dietary calcium and vitamin D intake reduces colorectal cancer risk.[4,5,9]

An association between folate intake through diet or supplements and colorectal cancer is complex, as data have shown both protective and tumor promoting effects.[4,9,19] However, the underlying basis for this is complex, particularly because alcohol use, smoking, genetic variants of the *methylenetetrahydrofolate reductase* gene, and other factors can interfere with folate metabolism. Thus, an adequate dietary folate intake may be enough to lower the risk of colorectal cancer, and exceeding normal intake may not be beneficial.

Deficiencies in other dietary micronutrients and antioxidants, including vitamin B_6, selenium, vitamin C, vitamin E, and carotenoids, may increase colorectal cancer risk, but there is no convincing evidence that the risk of colorectal cancer is greater in patients with low serum levels than in patients with adequate levels.[17,19]

PATHOPHYSIOLOGY

Anatomy and Bowel Function

The large intestine consists of the cecum; the ascending, transverse, descending, and sigmoid colon; and the rectum (Fig. 153-1). In adults, it extends about 1.5 m and has a diameter ranging from 8 cm in the cecum to 2 cm in the sigmoid colon. Absorption of fluid and solutes occurs in the right colon or the segments proximal to the middle of the transverse colon, with movement and storage of fecal material in the left colon and distal segments of the colon. Mucus secretion from goblet cells into the intestinal lumen lubricates the mucosal surface and facilitates movement of the dehydrated feces. It also serves to protect the luminal wall from bacteria and colonic irritants such as bile acids.

Four major tissue layers, from the lumen outward, form the large intestine: the mucosa, submucosa, muscularis propria, and serosa (Fig. 153-2). Embedded in the submucosa and muscularis propria is a rich lymphatic capillary system. Lymphatic channels do not extend into the mucosa. The muscularis propria consists of circular smooth muscle and outer longitudinal smooth muscle bands. Contraction of these muscle groups moves colonic material toward the anal canal. The outermost layer of the colon, the serosa, secretes a fluid that allows the colon to slide easily over nearby structures within the peritoneum. The serosa covers only the anterior and lateral aspects of the upper third of the rectum. The lower third lies completely extraperitoneal and is surrounded by fibrofatty tissue as well as adjacent organs and structures.

The surface epithelium of the colonic mucosa undergoes continual renewal, and complete replacement of epithelial cells occurs every 4 to 8 days. Cell replication normally takes place within the lower third of the crypts, the tubular glands located within the intestinal mucosa. The cells then mature and differentiate to either goblet or absorptive cells as they migrate toward the bowel lumen. The total number of epithelial cells remains relatively constant as the number of cells migrating from the crypts is balanced by the rate of exfoliation of cells from the mucosal surface. This two-phase process is critical to the malignant transformation of the epithelial cells. The number of dysplastic and hyperplastic aberrant crypt foci increases with increasing age; as the mass of abnormal cells accumulates at the top of the crypt and starts to protrude into the stream of fecal matter, their contact with fecal mutagens can lead to further cell mutations and eventual adenoma formation.

Colorectal Tumorigenesis

The development of a colorectal neoplasm is a multistep process involving several genetic and phenotypic alterations of normal bowel epithelium structure and function, leading to dysregulated cell growth, proliferation, and tumor development. Because most colorectal cancers develop sporadically, with no inherited or familial disposition, efforts have been directed toward identifying these alterations and learning whether detection of such changes may lead to improved cancer detection or treatment outcomes.

Features of colorectal tumorigenesis include genomic instability, activation of oncogene pathways, mutational inactivation or silencing of tumor-suppressor genes, genes associated with DNA repair, and activation of growth factor pathways.[20] During the early stages of tumorigenesis, emerging tumor cells expressing tumor antigens are eliminated by the immune system, which serves as an initial barrier to cancer progression.[21] These cells eventually escape immune surveillance as the tumor microenvironment becomes progressively immunosuppressive.

Genetic models have been proposed for colorectal tumorigenesis that describe a process of transformation from adenoma to carcinoma (Fig. 153-3).[20,22,23] The adenoma to carcinoma sequence of tumor development reflects an accumulation of mutations within colonic epithelium that confers a selective growth advantage to the affected cells. Key elements of this process include hyperproliferation of epithelial cells to form a small benign neoplasm or adenoma in conjunction with acquisition of various genetic mutations and epigenetic alterations that promote transformation to adenocarcinoma.[5,20,22]

FIGURE 153-3

Genetic changes associated with the adenoma–carcinoma sequence in colorectal cancer. The accumulation of genetic changes in the pathogenesis of colorectal cancer includes initiated by aberrant DNA methylation or MMR gene mutation with subsequent disruption in transforming growth factor-β receptor type II (TGF-β2R) and BAX signaling; mutation in the *APC* gene or abnormalities in β-catenin leading to inappropriate activation of the Wnt signaling pathway; mutational activation of COX-2 and impaired prostaglandin degradation from loss of 15-prostaglandin dehydrogenase (15-PGDH); *KRAS*, *PIK3CA*, or *BRAF* oncogene activation; increased EGFR signaling; and deletions or mutations of tumor suppressor genes *SMAD4*, *PTEN*, *P53*. Chromosomal instability (CIN) is a common feature of sporadic disease, but causative factors are not defined. Tumor-associated antigens (TAAs) expressed by emerging tumor cells are eliminated by the immune system during early tumorigenesis but eventually escape immune surveillance. The sequence of molecular events may differ between somatic and inherited genetic alterations. *(Data from References* 20,22, and 23.*)*

Two discrete adenoma to carcinoma progression sequences have been described, a traditional adenoma-carcinoma pathway (referred to as the chromosomal instability pathway) and the serrated neoplasia pathway.[5,22] Although both pathways share several genetic alterations, each has unique molecular and phenotypic characteristics. Table 153-2 lists important genetic mutations that are associated with colorectal cancers.[20,22,23]

TABLE 153-2

Genetic Mutations Associated with Colorectal Cancer

Type of Mutation	Disease	Genes	Comments
Germline	FAP	*APC*	Multiple adenomas and carcinomas in colon and rectum
	MYH-associated polyposis	*MYH*	Autosomal recessive syndrome; wide spectrum of degree of polyposis; frequent *KRAS* mutations
	Lynch syndrome	DNA MMR genes: *MSH2, MLH1, MSH6, PMS2, EpCAM*	Colorectal cancer in the absence of extensive polyposis; predisposition for endometrial, ovarian, gastric, hepatobiliary, urothelial, pancreatic, brain, and skin cancers
Somatic	Sporadic colorectal cancer	Oncogenes	
		KRAS	Mutations found in about 30%-50% of cancers
		NRAS	Mutations found in <5% of cancers
		BRAF	*BRAF* V600E mutation found in 5%-15% of cancers
		PIK3CA	Activating mutations found in 10%-20% of cancers
		EGFR	Gene upregulation in 30%-70% of cancers
		c-MYC	Elevated expression in 70%-80% with gene amplification/rearrangement in 10%-30% of cancers
		ERBB2 (known as HER2)	Gene amplification or mutation in 2%-7% of cancers
		SRC	Gene deregulated in up to 80% of cancers
		Tumor suppressor genes	
		P53	Loss or mutation in up to 60% of cancers
		SMAD4	Mutations in 3%-18% of cancers
		APC	Inactivated in up to 80% of sporadic cancers
		TGF-βR2	Inactivating mutations present in 20% of cancers; mutations in more than 90% of cancers with MSI
		PTEN	Frequency of inactivating mutations about 10% but loss of PTEN protein expression evident in 15%-20% of cancers

HER-2, human epidermal growth factor receptor 2; TGF-βR2, transforming growth factor-β receptor type II.

Data from References 20, 22 and 23.

Genomic Instability

Genomic instability is a hallmark of colorectal carcinogenesis, and presents as chromosomal instability (CIN) or MSI.[20] Three molecular pathways that lead to genomic instability are CIN, MSI, and CpG island methylator phenotype (CIMP) pathways. The CIN pathway accounts for about 85% of colorectal cancers, and typically follows genomic events initiated by a sporadic APC mutation, with subsequent activation of *RAS* or loss of *P53*.[22] Features of CIN include a high frequency of gene DNA amplifications/gains or deletions/losses and copy number alterations. Important consequences of CIN include imbalanced chromosome number (aneuploidy), chromosomal gene amplification, and loss of a wild-type allele of a tumor-suppressor gene, also referred to as loss of heterozygosity (LOH).

Up to 15% of colorectal cancers arise though the MSI pathway, which is caused by a disruption of DNA repair genes.[22] Microsatellites are a series of repeat nucleotide sequences that are spread out across the entire genome. Microsatellite replication errors within tumor DNA occur frequently, and mutations of the MMR genes that recognize and regulate DNA MMR errors contribute to MSI and colorectal tumorigenesis. Mutations in MMR genes can be inherited or developed by somatic causes. Germline mutation of MMR genes is an important characteristic of Lynch syndrome.

Alterations in gene expression or function in the absence of DNA sequence alterations are referred to as epigenetic changes, and these are usually due to methylation of DNA gene promoter regions or histone modifications.[22] The serrated neoplasia pathway (also referred to as the CIMP pathway) can lead to microsatellite stable and instable cancers. It accounts for 10%-20% of colorectal cancers, and is associated with epigenetic instability, *RAS* and *RAF* mutations. CIMP is characterized by hypermethylation of a panel of multiple genes that are associated with gene silencing and subsequent loss of tumor suppressor gene function.[5]

Growth Factor Signaling Pathways

Aberrant signaling of growth factor pathways plays an important role in colorectal tumorigenesis. Activation of prostaglandin signaling is an early step in the adenoma to carcinoma transformation process and is induced by upregulated expression of COX-2 and inflammation.[24] COX-2 mediates the synthesis of prostaglandin E2, which stimulates cancer growth. Furthermore, 80% of colorectal cancers have loss of 15-prostaglandin dehydrogenase, or 15-PGDH, the rate-limiting enzyme responsible for prostaglandin degradation. Dysregulated intracellular signal transduction from EGFR, a transmembrane glycoprotein involved in signaling pathways that affects cell growth, differentiation, proliferation, and angiogenesis, plays a key role in colorectal cancer pathogenesis and immune evasion in colorectal cancer. *EGFR* activation enables downstream signaling through the mitogen-activated protein kinase (MAPK)/RAS/RAF/MEK/ERK and PI3K/AKt/mTOR pathways, thereby promoting tumor differentiation, proliferation, progression, and survival.[22,24] EGFR is overexpressed in most colorectal cancers and high tumor EGFR overexpression is associated with a worse prognosis.[24] These mechanisms are relevant because of the availability of pharmacologic agents that can influence these signaling pathways and affect cell growth.

Oncogene and Tumor Suppressor Gene Alterations

Mutation or loss of the *APC* tumor suppressor gene is a key factor involved in tumor formation through constitutive activation of the Wnt signaling pathway, a mediator of cell-cycle progression, cell proliferation, differentiation, and apoptosis.[22] The *APC* gene encodes for APC protein that binds to and degrades cytoplasmic β-catenin, a downstream component of the Wnt signaling pathway. Inactivation of the *APC* gene is the single gene defect responsible for FAP and is frequently an initiating event in sporadic colorectal cancer.

Mutational inactivation of *P53* represents a frequent and key step in colorectal tumorigenesis, occurring in the majority of colorectal cancers.[22] Normal *P53* gene expression is important for G_1 cell-cycle arrest to facilitate DNA repair during replication and to induce apoptosis. An additional step in tumor progression is the mutational inactivation of the transforming growth factor-β (TGF-β) signaling pathway, which facilitates adenoma transition to high-grade dysplasia or carcinoma and also inactivates *SMAD4.* In normal epithelium, TGF-β has an antiproliferative role and induces growth arrest and apoptosis. Alterations in *SMAD4* or TGF-β receptors lead to a loss of the normal growth inhibitory response to TGF-β.

Several oncogene-activating mutations play an important role in promoting colorectal cancer.[22] Mutations in members of the *RAS* gene family—*KRAS*, *HRAS*, and *NRAS*—in addition to *BRAF*, activate the MAPK signaling pathway, which stimulates cell proliferation and other activities that promote carcinogenesis. *HER2* gene amplification/overexpression occurs infrequently in colorectal cancer, although *RAS* and *BRAF* wild-type tumors have a greater likelihood of having HER2 overexpression.[24] Mutations of *PIK3CA*, which encodes the catalytic subunit of a PI3K survival pathway, increase production of phosphatidylinositol-3,4,5-triphosphate, which influences cell growth, proliferation, and survival. Mutation or loss of *PTEN*, a tumor suppressor gene that antagonizes PI3K signaling, produces similar effects. Multiple additional genetic alterations contribute to carcinoma formation and metastases by altering cellular growth, metabolism, migration, and invasive capabilities, and angiogenesis.[22,24]

Histology

Adenocarcinomas account for about 92% of tumors of the large intestine and about 7% are classified mucinous adenocarcinoma.[4] The other histologic types, such as signet-ring adenocarcinoma, squamous cell carcinoma, and neuroendocrine carcinomas, are rare. Adenocarcinomas are assigned one of the three tumor grade designations based on the degree of cellular differentiation, the degree to which the tumor resembles the structure, and the function of its cell of origin. The most differentiated adenocarcinomas are low-grade tumors, whereas high-grade tumors are the most undifferentiated, and have frequently lost the characteristics of mature normal cells. Poorly differentiated tumors are associated with a worse prognosis than those that are relatively better differentiated.

Mucinous adenocarcinomas possess the same basic structure as adenocarcinomas but differ in that they secrete an abundant quantity of extracellular mucus. They tend to be frequent in patients with MMR tumor mutations. Signet-ring adenocarcinomas also have a characteristic appearance but are uncommon. Signet-ring histology occurs more frequently in individuals younger than 50 years of age, patients with ulcerative colitis, and tends to be present at a more advanced stage of disease at diagnosis. Both mucinous and signet-ring adenocarcinoma histologies confer a poor prognosis. Patients with neuroendocrine tumors and squamous cell carcinoma often present with distant metastases and also have a poor prognosis.

PREVENTION AND SCREENING

Cancer prevention efforts can be either primary or secondary. Primary prevention strategies aim to prevent the development of colorectal cancer in a population at risk. Secondary prevention approaches are undertaken to prevent malignancy in a population that has already manifested an initial disease process.

Chemoprevention

② Several agents have been evaluated as chemoprevention strategies for colorectal cancer, including prospective population-based screening trials of dietary fiber intake, and randomized controlled trials of calcium, vitamin D, and folate supplementation.[25-27] However, findings do not support their use now. Additional intervention trials of various micronutrients, epigenetic modulators, and other chemopreventive agents have been completed or are ongoing.[9,21,26,28-30] In addition, the most widely studied agents for the chemoprevention of colorectal cancer are aspirin, non-aspirin NSAIDs, and COX-2 selective inhibitors, but only aspirin is recommended for chemoprevention in some patients.[10,27,29] The effectiveness of these agents has been studied in high-risk individuals and within the general population.

In individuals with FAP, celecoxib, NSAIDs, and aspirin have been studied to delay the development of adenomatous polyps and to reduce polyp recurrence following colectomy with a retained rectum, but they are not viewed as alternatives to surgery.[25,26,29] In randomized controlled trials, celecoxib 400 mg orally twice daily as an adjunct to usual care significantly reduced the mean size and number of colorectal polyps after 6 to 9 months of treatment. However, the US Food and Drug Administration (FDA) approval for celecoxib was withdrawn because of lack of data showing long-term benefit. Sulindac induces adenoma regression but does not appear to delay or prevent malignancy. The benefits of these agents are transient because polyps increase in size and number within a few months after discontinuing treatment. These agents may be useful to reduce adenoma recurrence following surgery, but they are not recommended for chemoprevention.

② Non-aspirin NSAIDs and COX-2 inhibitors reduce the risk of sporadic and recurrent colorectal adenomas in cohort and case-control studies, and COX-2 inhibitors were also effective in controlled trials.[31] Celecoxib is associated with a 34% relative risk reduction in adenoma recurrence and 55% risk reduction in the incidence of advanced adenomas.[29,31] Optimal dosing, agents, and duration of treatment remain to be determined, and cardiovascular events in addition to the risk of gastric ulceration and bleeding with these agents are of concern. Although NSAIDs may be appropriate for selected individuals at high risk for colorectal cancer but low risk for cardiovascular disorders, the US Preventive Services Task Force (USPSTF) has concluded that potential harms associated with NSAID use (other than aspirin) outweigh benefits for prevention of colorectal cancer in the general population.[32]

The use of aspirin as both a primary and a secondary chemopreventive agent remains controversial. In patients with prior adenomas or diagnosis of colorectal cancer, regular daily aspirin use reduces colorectal adenoma recurrence, and colorectal cancer incidence and mortality.[29,30]

Aspirin reduces the risk of sporadic and recurrent adenomas by about 17% and advanced adenomas by 28%.[29,31] Higher aspirin doses reduced the risk of colorectal cancer over a 23-year follow-up period by 26% among the general population, but lower doses (75-300 mg) of daily aspirin for 5 years were also associated with a reduction in the risk of colorectal cancer and in 20-year mortality from colorectal cancer by 34%.[29,30] Individuals with Lynch syndrome who received aspirin 600 mg daily for at least 2 years experienced a 59% reduction in colorectal cancer risk that became evident 5 years after the aspirin was first started and had been discontinued.[29]

Although the optimal aspirin dose and treatment durations are unknown, increasing evidence supports a chemoprotective effect of aspirin in select high-risk individuals and in the general population. The extent of risk reduction appears to be inversely related to the duration of therapy and the chemopreventive effects of aspirin may be delayed by 5 to 10 years. However, the balance of risks and benefits with long-term aspirin use is unclear, and aspirin is only recommended for chemoprevention in some patients. The USPSTF guidelines endorse daily low-dose aspirin for at least 10 years in adults aged 50 to 59 years with a ≥10% 10-year cardiovascular disease risk, a life expectancy of at least 10 years, and who are not at risk for bleeding, for primary prevention of both cardiovascular disease and colorectal cancer.[32] Adults of age 60 to 69 years may also receive low-dose-daily aspirin for at least 10 years if the benefits outweigh the risks, and an individual risk calculation model could be useful to identify those individuals who would benefit most.[33] *PIK3CA* mutations, which are present in up to 20% of colorectal cancers, may also be a useful biomarker.[29] Among aspirin users with a history of colorectal cancer, those with tumor *PIK3CA* mutations experienced longer survival times compared to individuals without *PIK3CA*-mutated tumors.

Randomized controlled trials of calcium, vitamin D, and folate supplementation as chemoprevention have also been conducted, but findings do not support their use now.[28-30] Despite data from epidemiologic and preclinical studies that suggest a benefit from calcium and vitamin D supplementation, data from randomized clinical trials have been inconsistent. Individuals with adequate vitamin D levels and no known increased risk of colorectal cancer do not appear to benefit from calcium or vitamin D supplementation.[29] In two trials, folate supplementation was associated with a nonsignificant increase in adenoma recurrence. Based on these results, the use of folate supplementation to reduce colorectal cancer risk is not recommended now.[26]

Newer preventive strategies include metformin chemoprevention and gut microbiota modulation using prebiotics, probiotics, and other approaches. Metformin reduced risk of adenoma and colorectal cancer in patients with type 2 diabetes, but definitive randomized clinical trials are needed to establish its effects among populations with different risk.[29] Findings from two randomized, controlled trials of prebiotics and probiotics have shown beneficial alterations in colorectal cancer biomarkers, and further studies are warranted to confirm clinical benefit in colorectal cancer prevention.[34]

Surgical Resection

Surgical resection remains an option to prevent colon cancer in individuals at extremely high risk for its development.[35] Despite the effects of NSAIDs and COX-2 selective inhibitors on adenoma development and recurrence in individuals with FAP, their effects are incomplete, and surgical resection is necessary for cancer prevention for these high-risk individuals. Individuals with FAP who have polyposis on lower endoscopy screening examinations should undergo colectomy or proctocolectomy, typically starting around the age of 20 years. Because of the high incidence of metachronous (ie, consecutive development) cancers (45%) in patients with Lynch syndrome, prophylactic subtotal colectomy is recommended for individuals who are not candidates for routine close follow-up. Colonoscopic polypectomy, removal of polyps detected during screening colonoscopy, is considered the standard of care for all individuals to prevent the progression of premalignant adenomatous polyps to adenocarcinomas.

Screening

Colorectal cancer screening decreases mortality by detecting cancers at an early, curable stage, and by detecting and removing adenomatous polyps. Effectiveness of screening programs relies on participation, which is influenced by test access, costs, risk of complications, technical aspects, expected and perceived burden of the test, and the socioeconomic status and cultural beliefs of the participating individual.[33] Multiple screening recommendations for early detection of colorectal cancer have been established; differences exist in specific screening guidelines published by various organizations.[36-41] Structural (visual) tests detect colorectal polyps and cancer while fecal-based tests detect early cancer. This section reviews available screening techniques for colon and rectal cancer.

Colonoscopy

Colonoscopy facilitates examination of the entire large bowel to the cecum in most patients and allows for simultaneous removal of premalignant lesions. Although no randomized trials show that colonoscopy directly decreases colorectal cancer mortality, observational studies show that screening colonoscopy and polypectomy reduces the incidence in colorectal cancer by about 80%, with a 50% to 60% reduction in colorectal mortality.[25,39] Colonoscopy allows for greater visualization of the colon, but it involves sedation, complete bowel preparation, and is associated with greater risk and inconvenience to patients. Colonoscopy is considered the gold standard for colorectal screening because of its ability to detect and remove lesions in the proximal as well as distal colon.[25,39,42]

Flexible Sigmoidoscopy

Flexible sigmoidoscopy (FSIG) uses a 60-cm flexible sigmoidoscope to examine the lower half of the bowel to the splenic flexure for most patients and is thus capable of detecting 50% to 60% of cancers.[39] According to some randomized trials FSIG may decrease colorectal cancer incidence and mortality by 23% and 31%, respectively.[36,39] The combination of FSIG and a fecal-based test appears to improve sensitivity for lesions that will be missed by sigmoidoscopy alone, but the true benefit of this approach to general practice has not been established.[39] FSIG offers the advantage of not requiring sedation or extensive bowel preparation, but the entire colon cannot be examined with FSIG and suspicious lesions must be evaluated by colonoscopy.[42]

Computed Tomography Colonography

Computed tomography colonography, also referred to as *virtual colonoscopy*, is an imaging procedure that creates two- or three-dimensional images of the colon by combining multiple helical computed tomography (CT) scans.[36] Sedation is not required and initial tests show high sensitivity and specificity for detecting adenomas of at least 6 mm in size. However, the procedure requires complete bowel preparation and is associated with radiation exposure, and colonoscopy will still be necessary to remove detected lesions.[39,42] Individuals may find this method as a more acceptable option to colonoscopy or sigmoidoscopy, although the insufflation procedure can be associated with some discomfort.[5]

Fecal Occult Blood Tests

Fecal occult blood tests (FOBTs) detect occult blood in the stool that may be associated with bleeding adenomas or cancer. Results from randomized controlled trials of annual FOBT screening show a reduction in colorectal cancer mortality by 33%.[39] Unlike structural tests, FOBTs are noninvasive and do not require bowel preparation. However, they will not detect most polyps and may produce false-positive or false-negative results.[36,39] Two main methods are available to detect occult blood in the feces: guaiac-based FOBT (gFOBT) and fecal immunochemical tests (FITs), also known as immunochemical FOBT. gFOBTs detect pseudoperoxidase activity of heme in human blood. Because gFOBTs detect blood from any sources and some foods affect peroxidase activity, patients are instructed to avoid NSAIDs, red meat, vitamin C, and large amounts of citrus for at least 3 days before and through the testing period.

Several limitations associated with gFOBT screening are of concern. Many early-stage tumors do not bleed, or bleed intermittently, and therefore the false-negative rates can be high and are variable depending on the gFOBT product used. In addition, the test results may not be valid because the test is often poorly performed both in the home and in physician office settings.[36,39] However, these concerns are addressed by testing three successive stool samples. False-positive results can prove to be very expensive and inconvenient for a patient because of the follow-up tests required to confirm a positive result. Annual screening, preferably using a high-sensitivity gFOBT (eg, Hemoccult SENSA), is an acceptable option for individuals at average risk for colorectal cancer. It should be noted that FOBT conducted in conjunction with a digital rectal exam during an office visit is not considered adequate colorectal screening.

FITs were developed to reduce false-positive and false-negative test results associated with the gFOBT. FIT uses antibodies to detect the globin protein portion of human hemoglobin. Since globin is degraded by enzymes in the upper gastrointestinal tract, FIT is more specific for lower gastrointestinal bleeding. Also, no diet or medication restrictions are necessary and testing involves a single stool sample collection annually.[38] FIT is more accurate than gFOBT for detecting cancer and advanced adenomas, although colonoscopy identifies more adenomas.[39,42]

Stool DNA Screening Tests

Molecular screening strategies analyze stool samples for the presence of potential markers of malignancy in cells that are shed from premalignant polyps or adenocarcinomas in the bowel.[36,39] Adenomas and carcinomas can contain certain DNA mutations and markers of MSI that can be detected using multi-target stool DNA (mt-sDNA) testing. A combined FIT and mt-sDNA test is available that has improved sensitivity for advanced adenomas and sessile serrated polyps, but lower specificity compared to FIT.[33,36,39] The optimal appropriate screening interval is unclear, although it may be less frequent than annual FIT.[39] Like other stool-based tests, patients with positive test results should be followed up with a colonoscopy.

Capsule Colonography

Capsule colonography (CapC) is not approved for screening average-risk patients, but it is approved for colorectal imaging in patients who are not candidates for sedation or colonoscopy or who had a previous incomplete colonoscopy.[37,39] This procedure uses a wireless capsule device that is swallowed by the patient to examine the gastrointestinal tract, thereby avoiding risks associated with sedation and colonoscopy.

Serology Test

A *SEPT9* DNA methylated polymerase chain reaction (PCR)-based blood test is approved for colorectal cancer screening but is not recommended in US cancer screening guidelines. Methylated *SEPT9* DNA is a form of the *SEPT9* gene that distinguishes colorectal cancer from normal tissue and is found in circulating plasma with some colorectal cancers.[36] Although the test has low sensitivity for detecting colorectal cancer, it may be an alternative for individuals who refuse to undergo other screening tests.[39]

Screening Summary

③ Table 153-3 shows US screening guidelines for early detection of colorectal cancer with the goal of cancer prevention.[36-41] In recognition of the increasing incidence of colorectal cancer in adults younger than 50 years, the American Cancer Society, the National Comprehensive Cancer Network (NCCN), and the USPSTF recommend initiating colorectal cancer screening for individuals at average risk for colorectal cancer (their only risk factor is age greater than or equal to 45 years) at the age of 45 years.[36,38,39,42] Recommended programs for regular screening include a colonoscopy every 10 years, annually with a high-sensitivity gFOBT or FIT, or an FSIG every 5 years. Recommendations for screening procedures and schedules vary among organizations. The US Multi-Society Task Force on Colorectal Cancer, the American College of Gastroenterology, and the American College of Physicians recommend colorectal cancer screening in adults at average risk beginning at the age of 50 years, except in Black individuals, for whom evidence supports screening starting at the age of 45 years.[37,40,41]

Several screening methods are available, which have the potential to reduce colorectal cancer mortality, and because each method is associated with different benefits and potential harms, patient preferences and available resources should be considered for individual patients.[36,42] More aggressive (usually starting at an earlier age) screening recommendations are given for moderate-to-high risk individuals and colonoscopy is generally preferred for initial screening and surveillance following polyp removal in this population.[5,39] Most organizations recommend discontinuing screening and surveillance in populations when risk may outweigh benefit. Routine colorectal cancer screening is recommended for individuals up to the age of 75 years with a life expectancy ≥10 years, with individualized screening decisions made for individuals aged 76 to 85 years and discontinuing screening in adults older than 85 years.[36-42]

CLINICAL PRESENTATION AND DIAGNOSIS

Signs and Symptoms

The signs and symptoms associated with colorectal cancer can be extremely varied and nonspecific. Patients with early-stage colorectal cancer are often asymptomatic, and lesions are usually found through screening studies. Any change in bowel habits (eg, constipation, diarrhea, alteration in size or shape of stool), abdominal pain, or distension may be warning signs of a malignant process. Obstructive symptoms and changes in bowel habits frequently develop with tumors located in the transverse and descending colon. Rectal cancer may be associated with tenesmus, though bleeding is the most common symptom. Bleeding may be acute or chronic and can appear as bright red blood mixed with stool or melena. Iron-deficiency anemia, presenting as weakness and fatigue, can develop from chronic occult blood loss.

About 20% of patients with colorectal cancer present with metastatic disease.[1] Metastatic spread occurs in the setting of direct tumor invasion of the peritoneum or by lymphatic or hematogenous spread. The venous drainage of the colon and rectum influences the pattern of metastases most commonly seen. The most common site of metastasis is the liver followed by the lungs, and then bones, specifically the sacrum, coccyx, pelvis, and lumbar vertebrae. Liver metastases are present in 25% of patients at presentation, with another 25% to 30% of patients developing liver metastases in the following 2 to 3 years from diagnosis.[43]

CLINICAL PRESENTATION: Colorectal Cancer

General

- Patient symptoms are usually nonspecific and can vary drastically among patients.
- Most patients are asymptomatic.

Symptoms

- Change in bowel habits (generally an increase in frequency) or rectal bleeding.
- Constipation, depending on the location of the tumor.
- Nausea, vomiting, and abdominal discomfort.
- Fatigue may be present if anemia is severe.

Signs

- Blood in the stool is the most common sign in symptomatic patients.
- Hepatomegaly and jaundice in advanced disease.
- Leg edema is a consequence of lymph node involvement, thrombophlebitis, fistula formation, weight loss, and pain in the lower back or radiating down the legs may be indicative of widespread disease.

Laboratory Tests

- Positive guaiac stool test and anemia (iron deficiency) from blood loss.
- Elevated carcinoembryonic antigen (CEA; more likely in patients with higher stages at presentation).
- Elevated liver enzymes may be present with metastatic disease.

Workup

When a patient is suspected of having colorectal carcinoma, a complete history and physical examination should be performed. The patient history should include a past medical history and family history, especially noting the presence of inflammatory bowel disease, colorectal cancer, polyps, and familial clustering of cancers to assess risk for an inherited colorectal cancer syndrome, as well as a full medication history, including prescription, over-the-counter (OTC), and complementary or alternative therapies. A complete physical examination includes careful abdominal examination for the presence of masses or ascites, a rectal examination, and an assessment for possible hepatomegaly and lymphadenopathy. A breast and pelvic examination is recommended in all women.

Evaluation of the entire large bowel requires a total colonoscopy, which allows for tissue collection for histologic evaluation to provide a tissue diagnosis following the procedure. Patients with invasive cancer of the colon or rectum require a complete staging workup, which includes laboratory testing and imaging of the abdomen, pelvis, and chest. Baseline laboratory tests should be obtained and include a complete blood cell count, platelet count, international normalized ratio, prothrombin time, activated partial thromboplastin time, liver chemistries, renal function tests, and CEA level. Abnormal liver chemistry test results may suggest liver involvement with tumor, though normal levels do not preclude metastatic involvement. Iron studies (eg, serum ferritin, serum iron, and total iron-binding capacity) may identify iron deficiency in patients with anemia.

CEA belongs to a group of cell-surface glycoproteins termed *oncofetal proteins*, which are expressed during embryonic development and re-expressed on the cell surfaces of many carcinomas, particularly those originating from the gastrointestinal tract. CEA concentrations can be measured in the blood and can, therefore, potentially serve as a marker for colorectal cancer. Elevated CEA levels are more frequent in patients with metastatic disease, but not all colorectal cancers produce CEA. Several concomitant disease states are associated with an elevated CEA: liver diseases, gastritis, peptic ulcer disease, diverticulitis, chronic obstructive pulmonary disease, chronic or acute inflammatory conditions, and diabetes.[44] Most commercially available assays list a value of less than 5 ng/mL (μg/L) as the upper limit of normal. Although CEA measurement is too insensitive and nonspecific to be used as a screening test for early-stage colorectal cancer, it is the surrogate marker of choice for monitoring colorectal cancer response to treatment, particularly if the pretreatment concentration is elevated.[44] The CEA test may have preoperative prognostic implications because it correlates with the size and degree of differentiation of the carcinoma. Elevated preoperative CEA levels correlate with poor survival and may predict the likelihood of recurrence, regardless of tumor stage at diagnosis. However, it should not be used as an indication for adjuvant therapy. After a potentially curative resection, CEA levels should return to normal within 4 to 6 weeks. Persistently elevated CEA levels may indicate residual disease, while elevations after normalization may indicate relapsed disease.

Radiographic imaging studies are used to evaluate the extent of disease involvement for initial staging, and subsequently to monitor disease response to therapy. Contrast dye-enhanced CT scans of the chest, abdomen, and pelvis are performed to evaluate pulmonary, hepatic, and retroperitoneal involvement as well as occult abdominal and pelvic disease. In certain cases, such as patients with contrast dye allergies, magnetic resonance imaging (MRI) of the abdomen and pelvis may be substituted. A glucose analog [^{18}F]-fluorodeoxyglucose-positron emission tomography (PET) scan may also be performed as the primary imaging modality or to confirm metastatic disease if findings from CT or MRI scans are not conclusive. PET imaging may provide functional information to assist in discriminating between benign and malignant disease by detecting tumor-related metabolic alterations in affected tissues. PET scans are commonly used for the detection of recurrent colorectal cancer in patients with rising CEA levels and inconclusive findings on standard imaging studies. A PET scan is often performed in conjunction with a CT scan for anatomical localization of a lesion(s). For initial rectal cancer staging, assessment of the extent of tumor spread into the surrounding mesorectum and depth of invasion within the bowel wall may be performed using MRI or endorectal ultrasound.

Because of the increased likelihood of Lynch sndrome in patients diagnosed with colorectal cancer younger than the age of 50 years, MMR protein testing on the cancer specimen is recommended. The level of MMR protein expression can be determined by immunohistochemistry, which is decreased with MMR gene mutations. Gene sequencing can also be performed to detect MSI. If immunohistochemical analysis of the tumor reveals the absence of MLHI protein expression, *BRAF* gene mutation testing is recommended to distinguish between somatic and germline *MLH1* gene mutation. Individuals with abnormal MMR protein expression or MSI should be referred for genetic counseling as additional testing and cancer susceptibility risk assessment may be appropriate for themselves and family members.

Staging

Staging examinations determine the extent of disease, which allows the clinician to develop treatment plans and estimate overall prognosis. The same TNM classification system is used for both cancers of the colon and rectum since the categories reflect similar survival outcomes.[44,45] This classification assesses three aspects of cancer growth: T (tumor size or penetration), N (lymph node involvement), and M (presence or absence of metastases). The TNM classification also allows for various subdivisions within each of the three categories, which is then used to determine the disease stage. Table 153-4 summarizes the staging definitions used in the TNM system and corresponding 5-year survival rates.[44-46] Figure 153-4 shows the various stages of cancer based on cancer penetration through the bowel wall and extension to regional lymph nodes. An individual patient's stage is determined at the time of the initial diagnosis and does not change with progression of disease or recurrence. For example, if a patient is diagnosed with stage II colon cancer and later recurs with metastases to the liver, that patient is in stage II now with metastatic disease to the liver, not stage IV.

Primary Tumor (T)

T_{is}, Carcinoma in situ: intraepithelial or invasion of lamina propria with no extension through muscularis mucosae.

T_1, Tumor invades submucosa through the muscularis mucosa but not into the muscularis propria.

T_2, Tumor invades muscularis propria.

T_3, Tumor invades through the muscularis propria into pericolorectal tissues.

T_{4a}, Tumor invades through the visceral peritoneum, including bowel perforation through tumor and invasion of tumor through inflammatory surface of visceral peritoneum.

T_{4b}, Tumor directly invades or is adherent to other organs or structures.

Lymph Nodes (N)

N_0, no regional lymph node metastasis.

N_1, metastasis in 1-3 lymph nodes.

N_{1a}, metastasis in 1 lymph node.

N_{1b}, metastasis in 2-3 lymph nodes.

N_{1c}, tissue tumor deposits without lymph node metastasis.

N_2, metastasis in 4 or more lymph nodes.

N_{2a}, metastasis in 4-6 lymph nodes.

N_{2b}, metastasis in more than 7 lymph nodes.

Distant Metastasis (M)

M_0, no distant metastasis

M_{1a}, metastasis confined to one site or organ without peritoneal metastasis.

M_{1b}, metastasis in 2 or more sites or organs without peritoneal metastasis.

M_{1c}, metastasis to the peritoneal surface with/without metastasis to another site or organ.

[a]Survival for Stage IVA-C.

Data from References 44-46.

Prognosis

The stage of colorectal cancer upon diagnosis is the most important independent prognostic factor for survival and disease recurrence. Five-year survival is about 90% for individuals who present with a localized tumor stage at diagnosis as compared with about 14% for individuals with metastatic disease at diagnosis.[1]

Clinical factors present at the time of diagnosis that are associated with a poor prognosis and decreased survival include bowel obstruction or perforation, high preoperative CEA level, distant metastases, and location of the primary tumor in the rectum or rectosigmoid area.[47] Along with resection of the primary tumor, a minimum of 12 lymph nodes must be examined to accurately determine regional lymph node involvement and predict lymph node-negative disease. The pathologic assessment also includes determination of TNM stage, tumor type, and histologic grade, presence of venous, and lymphatic invasion, and whether the resected margins are free of tumor.[44] Consideration of these factors plays an important role in determining optimal strategies for treatment and appropriate follow-up. Additional morphologic tumor features that have been associated with adverse clinical outcome include infiltrative tumor border configuration, evidence of perineural invasion, extranodal tumor deposits, and presence of tumor budding, characterized by clusters of cells that possess properties of malignant stem cells and are associated with increased risk of local and distant spread.

Certain molecular markers, particularly MSI, 18q/*DCC* mutation or LOH, *BRAF V600E* mutation, and *RAS* mutations, are also associated with colorectal cancer prognosis, although the pathologic stage of disease remains the primary prognostic assessment.[44,48] Colorectal cancers with allelic LOH on chromosome 18q or absent DCC protein are associated with a worse prognosis within stages II and III disease, but data are insufficient to warrant use of this test in practice now.[49] MSI can be determined through DNA sequencing or by immunohistochemistry staining for protein products of the MMR genes. Colorectal cancers that demonstrate MSI-H appear to be associated with a more favorable outcome and do not benefit from adjuvant fluoropyrimidines for early-stage disease. Tumor DNA *BRAF* and *RAS* mutation status appears to be associated with overall survival but is not used to determine prognosis.

Although multiple prognostic biomarkers for colorectal cancer have been identified, single molecular tests other than MSI are not used routinely in clinical practice. However, several multigene assays have been developed that provide prognostic information to assist in identifying individuals at high risk for cancer recurrence from early-stage disease.[44,48] The Onco*type* DX colon cancer assay is commercially available and has been validated in several trials as a prognostic test for stages II and III colon cancer.[50,51] Gene expression profiles classify risk of recurrence as low, intermediate, or high, and these scores are prognostic for recurrence, disease-free survival, and overall survival. The ColoPrint gene expression assay characterizes the risk of recurrence as low or high, and is undergoing further validation in clinical trials.[44] The ability for these and other gene signature assays in development to predict which patients may benefit from adjuvant chemotherapy has not been well established.

TREATMENT

Desired Outcomes

Treatment goals for cancer of the colon or rectum are based on the stage of disease at presentation. Stages I, II, and III disease are considered potentially curable and the goal of management is to eradicate potential micrometastases after surgical resection. Based on the numbers and site(s) of metastases, about 20% to 30% of patients with metastatic colorectal cancer may be cured, if their metastases are considered resectable.[44] Most patients with stage IV disease are not curable, and treatments for metastatic disease are considered palliative to reduce symptoms, avoid disease-related complications, and prolong survival. However, special attention should be given to those with oligometastatic lesions in the liver or lung since potential cure is still possible for some of these patients.

General Approach

Performance status, concomitant disease states, lifestyle factors, patient preferences, and patient age (although advanced age is not an absolute contraindication for aggressive therapies) must be considered in the treatment planning process. Special or emergent conditions, such as bowel obstruction or perforation, severe pain, anemia, or other symptomatic problems, need to be addressed acutely, after which time a more long-term disease-specific plan can be developed. The treatment approaches for cancer of the colon or rectum reflect two primary treatment goals: curative therapy for localized disease and palliative therapy for metastatic cancer.

For patients for whom treatment intent is curative, surgical resection of the primary tumor is the most important component of therapy. Depending on the extent of disease and whether the tumor originated in the colon or rectum, further adjuvant chemotherapy or chemotherapy plus XRT (chemoradiation) may be appropriate. For selected patients with resectable metastases, surgical resection may be an option. However, for most patients with metastases, systemic chemotherapy is the mainstay of treatment; XRT may also be useful for disease palliation of localized symptoms. Patients with metastatic disease who are asymptomatic may benefit from initiation of therapy and continuous treatment should be considered.

Operable Disease

Surgery

④ Individuals with operable—stages I, II, and III—cancer of the colon or rectum should undergo complete surgical resection of the primary tumor mass with regional lymphadenectomy as a curative approach for their disease.[33] The surgical approach for colon cancer generally involves complete resection of the tumor with at least a 5-cm margin of tumor-free bowel and regional lymphadenectomy of at least 12 lymph nodes.

The preferred surgical procedure for rectal cancer is total excision of the mesorectum, the surrounding tissue containing perirectal fat and draining lymph nodes.[33,45] If the distal margin clear of tumor is at least 1 cm, sphincter-preserving surgery may be possible for patients with cancers in the middle and lower portion of the rectum. Individuals who are not candidates for sphincter-sparing resections or have extensive local spread of tumor will require an abdominoperineal resection. This involves removal of the distal sigmoid colon, rectosigmoid colon, rectum, and anus with the establishment of a permanent sigmoid colostomy.

Colectomies for colon cancer can be performed as open procedures or laparoscopically. Laparoscopic colectomy has become an accepted procedure for colon cancer.[44] This technique appears to produce similar results to conventional surgery, with the benefits of a smaller surgical incision, shorter hospital stay, shorter duration of ileus, and reduced pain. Complications associated with colorectal surgery include infection, anastomotic leakage, obstruction, adhesion formation, sexual dysfunction, and malabsorption syndromes, depending on the site and extent of resection. Complications affecting bowel function associated with surgery for rectal cancer increase as the level of anastomosis approaches the anus.

Neoadjuvant XRT for Colon Cancer

XRT has a limited role in colon cancer because most recurrences are extrapelvic and occur in the abdomen. A subset of patients with recurrent disease or with T_4 tumors that have penetrated fixed structures may benefit from neoadjuvant (preoperative) fluorouracil-based chemoradiation to improve resectability.[44] Adverse reactions associated with XRT in colon cancer can be acute or chronic. Acute effects primarily include hematologic depression, dysuria, diarrhea, abdominal cramping, and proctitis. Chronic symptoms that sometimes persist for months following discontinuation of XRT include persistent diarrhea, proctitis or enteritis, small bowel obstruction, perineal tenderness, sexual dysfunction, and impaired wound healing.

Adjuvant Chemotherapy for Colon Cancer

Adjuvant chemotherapy in colorectal cancer is administered after complete tumor resection in an attempt to eliminate residual micrometastatic disease, thereby decreasing tumor recurrence and improving survival rates. Patients should start adjuvant therapy as soon as they are medically stable following surgery because each 4-week delay results in a 14% decrease in overall survival.[44] Because more than 90% of patients with stage I colon cancer are cured by surgical resection alone, adjuvant therapy is not indicated.

Patients with stage II disease who are at higher risk for relapse should be offered adjuvant therapy, with a detailed discussion regarding the potential benefits versus treatment-related toxicities.[44] High-risk features include those with inadequate lymph node sampling, perforation of the bowel at presentation, poorly differentiated tumors, lymphovascular invasion, perineural invasion, inadequately sampled lymph nodes (<12 evaluated), T_4 lesions (stage IIB/IIC), and lesions with localized perforation or close or indeterminate margins. Individuals with MSI-H tumors have a better prognosis compared to those with MSI-L and may not benefit or even be harmed from adjuvant chemotherapy.

The presence of lymph node involvement with tumor places patients with stage III colon cancer at high risk for recurrence, and the risk of death within 5 years of surgical resection alone is as high as 70%, depending on the number of lymph nodes involved.[4] In this group of patients, adjuvant chemotherapy significantly decreases risk of cancer recurrence and death and is standard of care.

④ Standard adjuvant chemotherapy regimens include a fluoropyrimidine (fluorouracil [with leucovorin] or capecitabine) in combination with oxaliplatin (FOLFOX or CAPEOX) or administered alone (Table 153-5).[52-56] The addition of oxaliplatin is superior to fluoropyrimidines alone in stage III colon cancer, but this benefit has not been observed in stage II colon cancer.[44]

TABLE 153-5

Chemotherapy Regimens for the Adjuvant Treatment of Colorectal Cancer

Regimen	Agents	Comments
FOLFOX[52,53]	Oxaliplatin 85 mg/m^2 IV on day 1 Leucovorin 400 mg/m^2 IV on day 1 Fluorouracil 400 mg/m^2 IV bolus, after leucovorin on day 1, then 1,200 mg/m^2/day × 2 days CIV (total 2,400 mg/m^2 over 46-48 hr) Repeat every 2 weeks × 24 weeks[a,b]	Preferred regimen for stage III colon and rectal cancer high-risk stage colon cancer; common toxicities: sensory neuropathy, neutropenia
CAPEOX[53,54]	Oxaliplatin 130 mg/m^2 IV day 1 Capecitabine 1,000 mg/m^2 twice daily orally days 1 through 14 Each cycle lasts 3 weeks × 24 weeks[a,b]	Improved DFS in patients with stage III colon cancer compared to capecitabine alone or Roswell Park Regimen; common dose-limiting toxicities: neuropathies and hand-foot syndrome. A preferred regimen for adjuvant rectal therapy
Capecitabine[55]	Capecitabine 1,000 mg/m^2 to 1,250 mg/m^2 PO twice daily on days 1 through 14 Each cycle lasts 14 days and is repeated every 3 weeks × 24 weeks	Equivalent DFS as compared with the Mayo Clinic regimen with improved tolerability; hand-foot syndrome common, useful for patients without vascular access or who have difficulties with travel to infusion center
Roswell Park Regimen[56]	Leucovorin 500 mg/m^2 IV day 1 over 2 hr Fluorouracil 500 mg/m^2 IV bolus 1 hr after leucovorin Repeat weekly for 6 of 8 weeks × 4 cycles	Leukopenia common dose-limiting toxicity, diarrhea, and stomatitis common
Simplified Biweekly[44]	Leucovorin 400 mg/m^2 per day IV Fluorouracil 400 mg IV bolus, after leucovorin, then 1,200 mg/m^2/day days 1 and 2 (total 2,400 mg/m^2 over 46-48 hr) for 2 consecutive days Repeat every 2 weeks × 12 cycles	Hand-foot syndrome common

[a] Known as mFOLFOX6; survival benefit has not been demonstrated for patients 70 years and older.

[b] In patients with low-risk stage III (T1-3, any N), 3 months of CAPEOX is non-inferior to 6 months of CAPEOX for DFS but this has not been proven for FOLFOX. In patients with high-risk stage III disease (T4, N1-2, or any T, N2), 3 months of FOLFOX is inferior to 6 months of FOLFOX for DFS, but this has not been proven with CAPEOX. Grade 3 neuropathy is lower with 3 months of CAPEOX or FOLFOX.

CIV, continuous intravenous infusion; DFS, disease-free survival; OS, overall survival; PO, by mouth.

Data from References 44,52-56.

Fluorouracil Plus Oxaliplatin Regimens

④ NCCN guidelines recommend the FOLFOX (fluorouracil/leucovorin and oxaliplatin) regimen as the preferred treatment for patients with stage III colon cancer who can tolerate combination therapy.[44] These recommendations are based on results from the Multicenter International Study of Oxaliplatin/5-Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer (MOSAIC) trial, where the addition of oxaliplatin resulted in a 20% risk reduction in disease recurrence and increased 5-year disease-free survival (73% vs 67%) as compared with fluorouracil plus leucovorin alone.[52] With a median follow-up of 82 months, the addition of oxaliplatin resulted in an absolute 6-year overall survival difference of 2.5%. FOLFOX was associated with increased risk of paresthesia, neutropenia, and gastrointestinal toxicity (nausea, vomiting, and diarrhea) but toxicities were manageable with supportive care. This initial trial was performed with FOLFOX4 dosing schedule. Studies have further modified the regimen to improve tolerability and mFOLFOX6 regimen is now used.[44] A survival benefit has not been demonstrated for FOLFOX in patients with stage II colon cancer, but it is often used in stage II patients with multiple high-risk factors.[57]

⑤Toxicity associated with fluorouracil differs based on the dose, route, and schedule of administration. Leukopenia is the primary dose-limiting toxicity of IV bolus fluorouracil, although diarrhea, stomatitis, and nausea and vomiting can also occur.[58] The incidence and severity of stomatitis can be significantly reduced with the use of oral cryotherapy. In this approach, the patient is instructed to chew and hold ice chips in the mouth during the period between 5 minutes prior to and 30 minutes following the bolus injection of fluorouracil. The protective effects of this procedure are probably related to the local vasoconstriction caused by the ice chips, which temporarily reduces blood flow to the oral mucosa, thereby reducing drug exposure to the oral mucosa.

⑤Although continuous IV infusion fluorouracil is generally well tolerated, dose-limiting toxicities can be substantial. A distinct toxicity, palmar–plantar erythrodysesthesia (“hand-foot syndrome” or PPE), and stomatitis occur most frequently with this route of administration.[58] Hand-foot syndrome occurs in 24% to 40% of patients receiving extended continuous IV infusions and is characterized by painful swelling and erythroderma of the soles of the feet, palms of the hands, and distal fingers. The skin toxicity is fully reversible on interruption of therapy or dose reduction and is not life threatening, but it can be significant and acutely disabling. The risk of stomatitis, diarrhea, and hematologic toxicity is not substantial at standard doses, but it increases with increasing fluorouracil doses. No significant difference is noted in the incidence of mucositis, diarrhea, nausea and vomiting, or alopecia between continuous and bolus IV fluorouracil administration.

⑤An additional determinant of fluorouracil toxicity, regardless of the method of administration, is related to its catabolism and pharmacogenomic factors. DPD is the main enzyme responsible for the catabolism of fluorouracil to inactive metabolites. A rare pharmacogenetic disorder characterized by complete or near-complete deficiency of this enzyme has been identified in patients with cancer. Patients with this enzyme deficiency develop severe toxicity, including death, after fluorouracil administration. Molecular studies have identified a relationship between allelic variants in the *DPYD* gene (the gene that encodes DPD) and a deficiency in DPD activity.[44] An approved genetic test for *DPYD* polymorphisms is available to identify patients who would require lower fluorouracil doses to avoid severe toxicity, but pretreatment DPYD genotyping is not recommended.

The addition of leucovorin to fluorouracil regimens increases the binding affinity of the active fluorouracil metabolite to thymidylate synthase (TS), thus enhancing its cytotoxic activity. Leucovorin administration prior to fluorouracil is the most effective approach to enable intracellular-reduced folates to accumulate prior to fluorouracil administration. When leucovorin is unavailable, levoleucovorin, the active isomer of racemic leucovorin, can be substituted as an alternative. The recommended levoleucovorin dose is 50% of the leucovorin dose.[59]

⑤Oxaliplatin has minimal renal toxicity, myelosuppression, and nausea and vomiting when compared with other platinum-based drugs. Oxaliplatin is associated with both acute and persistent neuropathies.[60] The acute neuropathies occur within 1 to 2 days of dosing and resolve within 2 weeks. The neuropathies usually occur peripherally, but may also occur in the jaw and tongue. A rare acute syndrome of pharyngolaryngeal dysesthesia (1%-2% of patients) is characterized by subjective sensations of difficulty in swallowing and shortness of breath. Overall, acute neuropathies occur in about 90% of patients, and are precipitated or exacerbated by exposure to cold temperatures or cold objects. Thus, patients should be instructed to avoid cold drinks and use of ice, and to cover skin before exposure to cold environments or cold objects. Several prophylactic and treatment strategies have been studied with varying degrees of success. Persistent neuropathy is typically a cumulative adverse drug reaction occurring after 8 to 10 cycles. The neuropathy is characterized by paresthesia, dysesthesia, and hypoesthesia, but may also include deficits in proprioception that can interfere with daily activities (eg, writing, buttoning, swallowing, and difficulty walking as a result of impaired proprioception). Persistent neuropathy occurs in about one-half of patients receiving oxaliplatin but may improve or resolve with dosage reductions or cessation of oxaliplatin therapy.[44,60] Prophylaxis with calcium and magnesium infusions has not been proven effective. A “stop-and-go” approach where oxaliplatin is temporarily discontinued after 3 months of therapy (or sooner with significant neuropathic symptoms) with the other drugs continued reduces neurotoxicity without compromising antitumor activity and has been advocated.[44] Oxaliplatin can be reinitiated at disease progression in those patients who experience near complete resolution of neurotoxicity. Duloxetine may be used to treat painful neuropathy.

Fluorouracil/Leucovorin Regimens

The efficacy of bolus and continuous infusion schedules generally favor continuous infusion of fluorouracil, which is probably related to its short plasma half-life and S-phase specificity for optimal TS inhibition. Continuous IV infusions also permit increased fluorouracil dose intensity, which may account for the higher response rates observed with prolonged infusions of fluorouracil. Most commonly, fluorouracil is administered by both IV bolus injection and continuous IV infusion (eg, FOLFOX and simplified biweekly regimens; see Table 153-5).

Capecitabine Regimens

④Capecitabine can be used an alternative for fluorouracil in an attempt to improve the safety and ease of administration of the chemotherapy regimen. Capecitabine is converted to fluorouracil through a three-step activation process, the final step being activation by thymidine phosphorylase, which is present in greatest concentrations at the tumor site. These activation steps lead to about a threefold increase in tumor fluorouracil levels. CAPEOX prolonged 3-year disease-free survival (71% vs 67%) as compared to bolus fluorouracil alone in patients with stage III disease, but did not prolong overall survival.[61] Capecitabine is non-inferior to bolus fluorouracil and leucovorin in patients with stage III colon cancer.[55] Disease-free survival between the groups was equivalent, and safety was improved with capecitabine.

⑤The toxicities differ for the two regimens, with increased risks of neuropathies and hand-foot syndrome with CAPEOX and increased risk of neutropenia/neutropenic fever with fluorouracil-based regimens. The incidence of diarrhea and stomatitis is also decreased with capecitabine. Doses may need to be reduced in patients who experience adverse drug reactions. Patients with renal dysfunction can accumulate drug and often require dose modification. Capecitabine-based regimens are recommended when patients are unable to tolerate fluorouracil-based therapy.[44]

Selection of an Adjuvant Regimen

Selecting a specific regimen from those listed in Table 153-5 requires an assessment of several patient-specific factors, including the performance status of the patient, comorbid conditions that may exist, and patient preferences for treatment based on lifestyle factors that are important to the patient. If a clinical trial is not an option, most patients with a good performance status will receive FOLFOX. Some patients prefer to not receive IV chemotherapy and may choose CAPEOX. Single-agent capecitabine may be the preferred option for patients with preexisting neuropathies, such as diabetic patients, or those patients wishing not to receive IV chemotherapy for any other reason. Fluorouracil and leucovorin have limited use now but are an acceptable option for patients, with low risk or average-risk stage II disease or those who cannot receive oxaliplatin and are unable to tolerate or take oral capecitabine. For example, patients who develop severe hand-foot syndrome may tolerate IV bolus fluorouracil/leucovorin because the risk of this toxicity is minimal with this administration method.

Patient age should also be considered when selecting an appropriate regimen. Subset analysis of the Multicenter International Study of Oxaliplatin/5-Fluorouracil/Leucovorin in the Adjuvant Treatment of Colon Cancer (MOSAIC) and National Surgical Adjuvant Breast and Bowel Project (NSABP)-C07 trials have demonstrated no overall survival benefit from adding oxaliplatin to patients older than 70 years and these patients may be appropriate for fluoropyrimidine-based therapy alone.[52,62]

The usual length of adjuvant therapy is 6 months. Non-inferiority studies have compared 3 versus 6 months of therapy in an effort to minimize long-term toxicities, particularly neuropathy associated with FOLFOX and CAPEOX. According to the results of two meta-analyses 3 months of CAPEOX is non-inferior to 6 months of CAPEOX in terms of disease-free survival in patients with low-risk stage III disease, but the same results have not been proven for FOLFOX and overall survival results were not evaluated.[53] In patients with high-risk stage III disease, 6 months of FOLFOX is superior to 3 months (3-year disease-free survival 76% vs 72%; hazard ratio [HR] 1.27; 95% confidence interval [CI], 1.07-1.51), but this has not been evaluated with CAPEOX.[63] The incidence of grade 3 neuropathy is lower with 3 months of CAPEOX or FOLFOX. Therefore, it remains controversial whether 3 months of adjuvant therapy is appropriate for all individuals.

Adjuvant and Neoadjuvant Therapy for Rectal Cancer

⑥Rectal cancer involves those tumors found below the peritoneal reflection in the most distal 15 cm of the large bowel, and as such it is distinct from colon cancer in that it has a propensity for both local and distant recurrence. The higher incidence of local failure and overall poorer prognosis associated with rectal cancer is a result of anatomic limitations in excising adequate radial margins around the rectal tumor. Most patients with stage II or III rectal cancer should receive combined-modality therapy consisting of chemoradiation and fluoropyrimidine-based chemotherapy perioperatively for a total of 6 months.[45]

⑥Perioperative treatment can be accomplished with the use of neoadjuvant (preoperative) chemoradiation followed by surgery and adjuvant (postoperative) chemotherapy or total neoadjuvant therapy (fluoropyrimidine-based chemotherapy followed by chemo XRT (or vice versa) followed by surgery). FOLFOX or CAPEOX are the preferred fluoropyrimidine-based chemotherapy regimens, but fluorouracil and leucovorin combination regimens and capecitabine can be used.[45] Neoadjuvant chemoradiation significantly reduces local recurrence and has fewer toxicities, and improved sphincter-preserving surgeries as compared to postoperative chemoradiation.[45,64] However, some patients are unable to tolerate a typical 5- to 6-week chemoradiation regimen and may be more appropriate candidates for a short course of preoperative XRT alone.[45] Chemotherapy combined with XRT typically involves continuous infusion fluorouracil, oral capecitabine, or bolus fluorouracil and leucovorin; the addition of oxaliplatin to either fluoropyrimidine was associated with increased toxicities without clear improvements in complete remission rates or survival benefit.[45,64]

Metastatic Disease: Initial Therapy

Patients are generally classified as having resectable, potentially resectable, or unresectable metastatic disease. Surgery and XRT are used to manage isolated sites of tumor. Chemotherapy is used for disseminated disease and the primary treatment modality for unresectable metastatic colorectal cancer. Patients with resectable or potentially resectable metastases are candidates for multimodality therapy.[44,45] Tumor genotyping for *RAS* (*KRAS* and *NRAS*) and *BRAF* mutation status, *HER2* amplification, and determination of tumor MMR or MSI status (if not previously done) are recommended for patients at the time when metastatic disease is diagnosed to identify appropriate treatment options. Testing can also be performed on archived tissue samples obtained when the cancer was initially diagnosed.

Resectable (or Potentially Resectable) Metastatic Colorectal Cancer

⑦ Patients present with metastatic disease isolated to the liver or lung and who undergo resection of all metastatic and primary lesions (metastasectomy) have an increased probability of survival compared with those whose metastatic lesions remain unresected.[44] Therefore, strategies to increase the success rate of these resections (or convert unresectable lesions to resectable) are used in these patients. Neoadjuvant chemotherapy, also referred to as conversional chemotherapy, is the primary method to increase complete resection rates in both patients with resectable or potentially resectable liver or lung lesions. In some cases, individuals with metastatic disease initially deemed unresectable may achieve significant tumor regression following neoadjuvant chemotherapy to then be considered for surgery.

The optimal sequencing of chemotherapy for patients with initially resectable metastatic disease is controversial, as treatment options include surgery followed by chemotherapy or perioperative (pre- and postoperative) chemotherapy with surgery.[44,45] Because of the high risk of recurrence following resection of metastases, postoperative chemotherapy is always recommended. Administration of both pre- and postoperative chemotherapy is common practice, but the risk of hepatotoxicity associated with preoperative chemotherapy should be considered. Irinotecan-containing regimens can cause steatohepatitis and oxaliplatin-containing regimens can cause vascular sinusoidal obstructive liver injury.[44] Therefore, surgery is performed as soon as possible after the disease becomes resectable and preoperative chemotherapy is limited to a 2- to 3-month time period while patients undergo close monitoring.

The choice of neoadjuvant therapy depends on patient-specific factors and includes regimens such as FOLFOX, CAPEOX, FOLFIRI (infusional fluorouracil, leucovorin, and irinotecan), or FOLFOXIRI (infusional fluorouracil, leucovorin, oxaliplatin, and irinotecan). It is typically administered for 2 to 3 months before surgery. Adjuvant chemotherapy (preferably FOLFOX or CAPEOX) should be administered to patients to complete a total of 6 months of chemotherapy (pre- and postoperative).[44]

Patients with unresectable lesions are eligible for the same chemotherapy regimens. However, because the primary goal is surgical resection whenever possible, patients should be evaluated for possible resection after every 2 months of therapy. If resection occurs, adjuvant chemotherapy should be administered to complete a total of 6 months of chemotherapy.

Hepatic-Directed Therapies

Hepatic-directed therapy, in addition to or as an alternative to surgical resection, can be considered in individuals with liver-only or liver-predominant metastatic disease. Hepatic artery infusion involves the placement of a permanent access catheter to the hepatic artery through which chemotherapy can be infused directly into the liver.[44] This approach offers the advantage of delivering high drug concentrations to tumors locally, thereby limiting systemic toxicities. Floxuridine with dexamethasone and fluorouracil with or without leucovorin are the most commonly used agents. Hepatic artery infusion is associated with potential biliary toxicity and the technical expertise required warrants use in selected patients by experienced practitioners. XRT can also be given to sites of hepatic tumor with external beam XRT or percutaneous arterial injection of micron-sized embolic particles loaded with a radioisotope (radioembolization). Other less common methods include tumor ablation procedures using radiofrequency ablation or microwave energy to generate heat that destroys localized tumor cells. Cryoablation can also be used, which includes placement of a cryoprobe into the tumor, either percutaneously or intraoperatively, and then lowering the probe temperature to −20°C to −40°C and rewarming it in cycles, resulting in formation of an ice ball that causes tumor destruction. These strategies may be useful for patients who have very small hepatic lesions and are unable to undergo liver resection surgery, but they are less successful than surgical interventions.

Unresectable Metastatic Colorectal Cancer

Unless the primary tumor is causing an obstruction, surgery in patients with established unresectable disease is rarely indicated. XRT may be useful to control localized symptoms in patients with metastatic colorectal cancer. Systemic chemotherapy palliates symptoms and improves survival in patients with unresectable disease. Common treatment regimens include combination of cytotoxics and a biologic agent.

Chemotherapy

⑦ Several chemotherapy regimens are acceptable for initial treatment of metastatic colorectal cancer.[44] The goals of therapy, history of prior chemotherapy, tumor genotype status, performance status/comorbidities, and risk of drug-related toxicities should be considered when an appropriate management strategy is defined for each individual. Treatment regimens are the same for metastatic cancer of the colon and rectum. Table 153-6 lists common initial chemotherapeutic regimens for metastatic disease.[44,45]

TABLE 153-6

Initial Chemotherapeutic Regimens for Metastatic Colorectal Cancer[a]

Regimen	Agents	Major-Dose Limiting Toxicities	Comments
Patients Appropriate for Intensive Therapy with *RAS* Mutations			
FOLFOX +/– bevacizumab	Oxaliplatin 85 mg/m^2 IV day 1 Leucovorin 400 mg/m^2 IV day 1 Fluorouracil 400 mg/m^2 IV bolus, after leucovorin day 1, then 1,200 mg/m^2/day × 2 days CIV (total 2,400 mg/m^2 over 46-48 hr) Repeat every 2 weeks +/– Bevacizumab 5 mg/kg IV day 1 before FOLFOX Repeat cycle every 2 weeks	FOLFOX: sensory neuropathy, neutropenia Bevacizumab: hypertension, thrombosis, proteinuria	Most commonly used first-line regimen
CAPEOX +/–	Oxaliplatin 130 mg/m^2 IV day 1	CAPEOX: diarrhea, hand-	Reduced capecitabine dose better

bevacizumab	Capecitabine 1,000 mg/m^2 orally twice a day, days 1-14 Repeat cycle every 3 weeks +/− Bevacizumab 7.5 mg/kg IV day 1 Repeat cycle every 3 weeks	foot syndrome, neuropathies Bevacizumab: hypertension, thrombosis, proteinuria	tolerated; patient must be able to be adherent and report adverse drug reactions in a timely fashion
FOLFIRI +/− bevacizumab	Irinotecan 180 mg/m^2 IV day 1 Leucovorin 400 mg/m^2 IV day 1 Fluorouracil 400 mg/m^2 IV bolus, after leucovorin day 1, then 1,200 mg/m^2/day × 2 days CIV (total 2,400 mg/m^2 over 46-48 hr) +/− Bevacizumab 5 mg/kg IV day prior to FOLFIRI Repeat cycle every 2 weeks	FOLFIRI: diarrhea, mucositis, neutropenia Bevacizumab: hypertension, thrombosis, proteinuria	May be preferred in patients who have preexisting neuropathy or those in which neuropathy may be debilitating to their line of work (eg, musician)
FOLFOXIRI +/− bevacizumab	Irinotecan 165 mg/m^2 IV day 1 prior to oxaliplatin Oxaliplatin 85 mg/m^2 IV prior to leucovorin day 1 Leucovorin 400 mg/m^2 IV day 1 prior to fluorouracil Fluorouracil 1,200 mg/m^2/day × 2 days CIV (total 2,400 mg/m^2 over 48 hr) Repeat cycle every 2 weeks +/− Bevacizumab 5 mg/kg IV day 1 before FOLFOXIRI Repeat cycle every 2 weeks	FOLFOXFIRI: neutropenia, diarrhea, stomatitis, peripheral neurotoxicity, thrombocytopenia Bevacizumab: hypertension, thrombosis, proteinuria	[b]More neutropenia and peripheral neurotoxicity compared to FOLFIRI; often used in medically fit individuals with diffuse aggressive disease to palliate symptoms and as potential conversion therapy
Patients Appropriate for Intensive Therapy with *RAS* or *BRAF* Wild-Type and Left-Sided Colon Tumors			
FOLFOX + cetuximab or panitumumab	FOLFOX regimen + cetuximab (400 mg/m^2 IV loading dose, then cetuximab 250 mg/m^2 IV weekly thereafter OR cetuximab 500 mg/m^2 IV every 2 weeks) before FOLFOX OR FOLFOX regimen + panitumumab 6 mg/kg IV day 1 before FOLFOX Repeat cycle every 2 weeks	FOLFOX: sensory neuropathy, neutropenia Cetuximab: Papulopustular and follicular rash, asthenia, constipation, diarrhea, allergic reactions, hypomagnesemia Panitumumab: rash, diarrhea, hypomagnesemia	Only *RAS* or *BRAF* wild-type and left-sided tumor
FOLFIRI + cetuximab or panitumumab	FOLFIRI + cetuximab (400 mg/m^2 IV loading dose, then cetuximab 250 mg/m^2 IV weekly thereafter OR cetuximab 500	FOLFIRI: diarrhea, mucositis, neutropenia Cetuximab:	Only *RAS* or *BRAF* wild-type and left-sided tumor; preferred for patients with preexisting neuropathy or those in whom

	mg/m^2 IV every 2 weeks) before FOLFIRI OR FOLFIRI + panitumumab 6 mg/kg IV day 1 before FOLFIRI Repeat cycle every 2 weeks	papulopustular and follicular rash, asthenia, constipation, diarrhea, allergic reactions, hypomagnesemia Panitumumab: rash, diarrhea, hypomagnesemia	neuropathy may be debilitating to their line of work (eg, musician)
Patients NOT Appropriate for Intensive Therapy with *RAS* Mutations			
Infusional fluorouracil + leucovorin +/− bevacizumab	Fluorouracil 400 mg/m^2 IV bolus, after leucovorin on day 1, then 1,200 mg/m^2/day × 2 days CIV (total 2,400 mg/m^2 over 46-48 hr) Repeat cycle every 2 weeks +/− Bevacizumab 5 mg/kg IV day 1 prior to fluorouracil and leucovorin Repeat cycle every 2 weeks	Infusional fluorouracil/leucovorin: neutropenia, diarrhea Bevacizumab: hypertension, bleeding, proteinuria	Infusional fluorouracil/leucovorin regimen preferred to bolus fluorouracil regimen
Capecitabine +/− bevacizumab	Capecitabine 850-1,250 mg/m^2 orally twice a day, days 1-14 +/− Bevacizumab 7.5 mg/kg IV day 1 Repeat cycle every 3 weeks	Capecitabine: hand-foot syndrome, diarrhea, hyperbilirubinemia Bevacizumab: hypertension, thrombosis, proteinuria	
Patients NOT Appropriate for Intensive Therapy with *RAS* or *BRAF* Wild-Type and Left-Sided Tumors			
Cetuximab[c]	Cetuximab 400 mg/m^2 IV loading dose, then cetuximab 250 mg/m^2 IV weekly thereafter Or Cetuximab 500 mg/m^2 IV every 2 weeks	Papulopustular and follicular rash, asthenia, constipation, diarrhea, allergic reactions, hypomagnesemia	Only *RAS* or *BRAF* wild-type and left-sided tumor
Panitumumab[c]	6 mg/kg IV over 60 minutes every 2 weeks	Rash, diarrhea hypomagnesemia, rare allergic reactions	Only *RAS* or *BRAF* wild-type and left-sided tumor
Patients with dMMR or MSI-H			
Pembrolizumab	2 mg/kg IV every 2 weeks or 200 mg IV every 3 weeks or 400 mg IV every 6 weeks[d]	Immune-mediated adverse drug reactions (most common: skin, liver, kidney, gastrointestinal tract, lung and endocrine systems)	Only in MMR-d or MSI-H tumors. Patients should be closely monitored for adverse drug reactions and report any adverse drug reactions immediately as interruption of treatment or initiation of corticosteroids may be needed

Nivolumab +/- ipilimumab	Nivolumab 3 mg/kg IV over 30 minutes and ipilimumab 1 mg/kg IV over 30 minutes every 3 weeks × 4 doses, then nivolumab 3 mg/kg IV or nivolumab 240 mg IV every 2 weeks or 480 mg IV every 4 weeks[d]	Immune-mediated adverse drug reactions (most common: skin, liver, kidney, gastrointestinal tract, lung and endocrine systems)	Only in MMR-d or MSI-H tumors. Patients should be closely monitored for adverse drug reactions and report any adverse drug reactions immediately as interruption of treatment or initiation of corticosteroids may be needed
Patients NOT Appropriate for Intensive Therapy with *HER*-Amplified and *RAS* and *BRAF* WT			
Trastuzumab + (pertuzumab or lapatinib) or fam-trastuzumab deruxtecan-nxki	Trastuzumab 8 mg/kg IV day 1 of cycle 1 then 6 mg/kg IV every 21 days + pertuzumab 840 mg IV day 1 of cycle 1 then 420 mg IV every 21 days OR trastuzumab 4 mg/kg IV day of cycle 1 then 2 mg/kg IV weekly + lapatinib 1,000 mg po daily OR fam-trastuzumab deruxtecan-nxki 6.4 mg/kg IV on day 1 every 21 days	Trastuzumab + pertuzumab: hypokalemia, abdominal pain, diarrhea, fatigue, nausea; trastuzumab + lapatinib: fatigue, elevated liver enzymes, diarrhea, and rash; fam-trastuzumab deruxtecan-nxki, interstitial pneumonitis	Only in *HER*-amplified and *RAS* and *BRAF* WT tumors. Evaluate all patients for left ventricular ejection fraction at baseline and monitor closely throughout therapy. Do not substitute conventional or biosimilar trastuzumab with ado-trastuzumab emastine, fam-trastuzumab deruxtecan or trastuzumab/hyaluronidase

[a] NCCN Guideline recommendations for initial therapy. All recommendations are category 2A unless otherwise noted. Category 2A: based on lower-evidence, there is uniform NCCN consensus that intervention is appropriate.

[b] Original dosing was 1,600 mg/m^2/day but it is recommended that US patients use this dose as they do not tolerate fluorouracil as well.

[c] NCCN Category 2B: based upon lower-evidence, there is NCCN consensus that this intervention is appropriate.

[d] Flat dosing is preferred.

Data from References 44,45.

Most metastatic colorectal cancers are incurable, and treatment goals are to control cancer growth, reduce patient symptoms, improve quality of life, and extend survival. The benefit of palliative chemotherapy for metastatic colorectal cancer as compared to observation or supportive care alone with regard to these treatment goals has been established. According to results from multiple randomized trials and meta-analyses, chemotherapy prolongs life and improves quality of life of patients with metastatic colorectal cancer.[33,44,45]

Most first-line chemotherapy regimens for metastatic colorectal cancer incorporate a fluoropyrimidine. Irinotecan or oxaliplatin added to a fluoropyrimidine-based regimen significantly improves response rates, progression-free survival, and median survival.[44,45] The addition of the targeted anti-angiogenesis agent bevacizumab further improves response rate and survival. Patients considered appropriate for initial intensive chemotherapy usually receive an oxaliplatin or irinotecan-containing regimen with infusional fluorouracil plus leucovorin and bevacizumab (unless contraindicated) or an EGFR inhibitor (if their tumors are left-sided and express *RAS* and *BRAF* wild-type). Capecitabine can be substituted for fluorouracil and leucovorin. If the patient has dMMR or MSI-H, they may receive immunotherapy. Patients who are not appropriate candidates for initial intensive therapy may be treated with fluoropyrimidine monotherapy with or without bevacizumab, EGFR inhibitor monotherapy (if their tumors are left-sided and express *RAS* and *BRAF* wild-type) immunotherapy if they have dMMR or MSI-H, or trastuzumab + pertuzumab or lapatinib or fam-trastuzumab deruxtecan-nxki (if their tumors have human epidermal growth factor receptor-2 [HER2] amplification and *RAS* and *BRAF* wild-type), as appropriate.[44] Patients may receive multiple different regimens; the sequence of drugs used appears less important than exposure to all active agents during the course of cancer treatments. Please refer "Adjuvant Chemotherapy for Colon Cancer" section for more information on the toxicities of the regimens used in both the adjuvant and metastatic settings.

Fluorouracil can be administered as an IV bolus, a continuous infusion, or a combination of the two in the metastatic setting. Continuous IV infusion fluorouracil regimens increase the duration of drug exposure during the S-phase of the cell cycle, increase cytotoxicity, and are better tolerated than bolus administration. When combined with irinotecan or oxaliplatin, infusional fluorouracil is recommended because of improved efficacy.[44]

Unlike in the adjuvant setting, irinotecan added to fluorouracil plus leucovorin as initial therapy for metastatic disease improves tumor response rates, time-to-progression, and overall survival.[65] ⑤The most common adverse drug reactions of irinotecan in these regimens are diarrhea, neutropenia, nausea and vomiting, dehydration, asthenia, abdominal pain, and alopecia; diarrhea and neutropenia are dose limiting. Two distinct patterns of diarrhea have been described. Early-onset diarrhea occurs during or within 2 to 6 hours after irinotecan administration and is characterized by lacrimation, diaphoresis, abdominal cramping, flushing, and/or diarrhea. These cholinergic symptoms, thought to be caused by inhibition of acetylcholinesterase, respond to atropine 0.25 to 1 mg given IV or subcutaneously. About 10% of patients experience acute symptoms during or shortly following the irinotecan. More commonly, late-onset diarrhea occurs 1 to 12 days after irinotecan administration and may last for 3 to 5 days. Late-onset diarrhea may require hospitalization or discontinuation of therapy, and fatalities have been reported. The risk of late-onset diarrhea can be decreased with aggressive antidiarrheal intervention. Aggressive intervention with high-dose loperamide therapy should consist of 4 mg taken at the first sign of soft or watery stools, followed by 2 mg orally every 2 hours until symptom-free for 12 hours; this regimen can be modified to 4 mg taken orally every 4 hours during the night.

⑤The severity of delayed diarrhea is correlated with the systemic exposure (ie, area under the concentration-vs-time curve) of irinotecan and SN-38 (irinotecan's active metabolite) and with genetic polymorphisms in the enzyme UGT1A1, which is responsible for the glucuronidation of SN-38 to inactive metabolites. Reduced or deficient levels of the UGT1A1 enzyme are observed in Gilbert syndrome, a familial hyperbilirubinemia disorder, and correlate with irinotecan-induced diarrhea and neutropenia.[66] FDA-approved testing to determine *UGT1A1* genotype is commercially available. Although some individuals advocate testing *UGT1A1* genotype prior to starting irinotecan, widespread testing has not been adopted.[44,67] The prescribing information recommends considering a reduced dose of irinotecan in patients with *UGT1A1*28* genotype.

Oxaliplatin, in combination with infusional fluorouracil plus leucovorin, is FDA-approved for use in first-line and salvage regimens for metastatic colorectal cancer. Oxaliplatin incorporation into fluorouracil-based regimens as first-line therapy for metastatic colorectal cancer is associated with higher response rates and prolonged progression-free survival, with variable effects on overall survival.[68] Oxaliplatin is not effective as a single agent in colorectal cancer and is therefore only used in combination regimens.

To further improve survival rates achieved with FOLFOX and FOLFIRI regimens, a four-drug regimen (FOLFOXIRI) was developed and has been compared with FOLFIRI. FOLFOXIRI improved progression-free survival and overall survival compared to FOLFIRI, and a higher proportion of patients receiving FOLFOXIRI were able to undergo radical resection of metastases.[44] As expected, FOLFOXIRI causes more neutropenia, neurotoxicity, diarrhea, and alopecia, but may be appropriate for medically fit individuals with diffuse aggressive disease to palliate symptoms and as potential conversion therapy.

Capecitabine is an oral, tumor-activated, and tumor-selective fluoropyrimidine carbamate. Capecitabine can be administered alone or in combination with oxaliplatin (CAPEOX, also known as XELOX). When administered alone, it has higher response rates but comparable time-to-progression and median survival to fluorouracil/leucovorin. CAPEOX has similar progression-free and overall survival when compared with FOLFOX.[69] Hand-foot syndrome is common with capecitabine, while grades 3 or 4 neutropenia and stomatitis are more common with fluorouracil plus leucovorin. The convenience of oral administration and different toxicity profile make capecitabine a useful alternative to infusional fluorouracil in regimens for metastatic disease.

Targeted Therapy

Guidelines and clinical practice recommend the addition of targeted therapy to one of the chemotherapy backbones mentioned earlier.[44]

⑧ Bevacizumab is a recombinant, humanized monoclonal antibody that inhibits vascular endothelial growth factor (VEGF). A modest increase in progression-free and overall survival benefit occurs when bevacizumab is combined with chemotherapy as compared with chemotherapy alone.[44] However, bevacizumab results in higher treatment-related mortality than chemotherapy alone (relative risk 1.33; 95% CI, 1.02-1.73) because of hemorrhage (24%), neutropenia (12%), and gastrointestinal perforation (7%).[70]

Hypertension is also common with bevacizumab.[44] The hypertension is easily managed with oral antihypertensive agents. Bleeding, thromboembolism, and proteinuria can also occur with bevacizumab. Proteinuria is monitored with urine dipsticks regularly during therapy, and the therapy is withheld in patients with 2+ protein or more, confirmed with a 24-hour urine collection. The risk of gastrointestinal perforation is increased by the addition of bevacizumab and extensive prior intra-abdominal surgery. Patients complaining of abdominal pain associated with vomiting or constipation should be evaluated for this rare but potentially fatal complication. Bevacizumab is also associated with a twofold increased risk of arterial thrombotic events, with patients who are older than 65 years or who have a prior history of arterial thrombotic events at greatest risk. Since bevacizumab can also interfere with wound healing, there should be at least a 6- to 8-week interval between the last dose of bevacizumab and elective surgery and wait at least 6 to 8 weeks to reinitiate bevacizumab after surgery. Necrotizing fasciitis can occur following wound healing or gastrointestinal perforation.

⑨ Cetuximab and panitumumab are monoclonal antibodies directed against EGFR. EGFR inhibitors may be used in combination with first-line chemotherapy regimens FOLFOX or FOLFIRI, or administered as single agents, but should not be combined with bevacizumab because of increased toxicity and no efficacy benefit.[44] The benefit of EGFR inhibitors, however, is limited to patients with wild-type *RAS* and *BRAF* tumors and they should not be used in patients with tumor *RAS* or *BRAF* mutations. Furthermore, patients with left-sided primary tumors have improved overall survival when treated with EGFR inhibitors while those with right-sided tumors (cecum to hepatic flexure) do not. Because fewer than 60% of patients with wild-type *KRAS* tumors respond to cetuximab or panitumumab, additional factors downstream of *RAS* signaling have been explored for their ability to predict response to EGFR inhibitors, including *BRAF* V600E mutation, and mutation or loss of *PTEN* or *PIK3CA.* Tumors with wild-type *KRAS*/*NRAS* and *BRAF* V600E mutation do not respond to anti-EGFR antibodies. The only situation where this might be beneficial is if the EGFR is administered in combination with a BRAF inhibitor, but now this has only been recommended after failure of the first-line setting (see "Metastatic Disease: Second-Line and Subsequent Therapy" section).

Severe infusion reactions, including anaphylaxis, can occur with cetuximab (3%) and panitumumab (1%).[44] Administration of panitumumab seems feasible in those who experienced a reaction with cetuximab.[71] Skin toxicity is also a common adverse drug reaction with these drugs and is not part of the infusion reaction. The presence of papulopustular skin rash correlates with response and survival. It most commonly occurs within 2 to 4 weeks of therapy initiation and preventative therapy with topical corticosteroids with moisturizer, sunscreen, and oral doxycycline is recommended unless contraindications exist.[72] Both these agents have also been associated with diarrhea and hypomagnesemia, which can occur even after discontinuation of the drug.

Trastuzumab and pertuzumab are monoclonal antibodies directed against HER2. Fam-trastuzumab deruxtecan-nxki is, and antibody drug conjugate with a trastuzumab backbone, linked to cytotoxic chemotherapy. Lapatinib is an oral tyrosine kinase inhibitor of both HER2 and EGFR1 receptors. A two-drug combination, trastuzumab + pertuzumab or lapatinib, or fam-trastuzumab deruxtecan-nxki alone is recommended as an option for patients with HER2 amplification and wild-type *RAS* and *BRAF* tumors.[44,45] Typically, they are reserved for second-line or subsequent therapy unless the patients cannot tolerate intensive therapy in the first-line setting (see "Metastatic Disease: Second-Line and Subsequent Therapy" section).

Immunotherapy

⑩ Immunotherapy is effective in dMMR tumors because these tumors encode mutant proteins and have the potential to be recognized and targeted by the immune system. Because the immune system can become suppressed when programmed death-ligands 1 and 2 (PD-L1 and PD-L2) on tumor cells bind to programmed cell death protein (PD-1) receptors on T cells, the use of PD-1 inhibitor drug therapy is reasonable in these tumors. The PD-1 inhibitor nivolumab has also been evaluated in combination with ipilimumab, a cytotoxic-T-lymphocyte-associated protein 4 (CTLA4) inhibitor; these drugs act synergistically to promote T-cell antitumor activity.[73] For more information about these therapies, see "Metastatic Disease: Second-Line and Subsequent Therapy" section.

Selection of an Initial Metastatic Regimen

Several factors should be considered when selecting first-line therapy for metastatic colorectal cancer when disease palliation is the primary treatment goal. The first consideration is whether intensive therapy is appropriate for the patient. Those with multiple comorbidities or low performance status would likely better tolerate less-intensive therapy. The second consideration is *RAS* and *BRAF* status and side of tumor involvement. Those with wild-type *RAS* and *BRAF* and left-sided tumors can receive an EGFR inhibitor therapy. Patients with dMMR or MSI-H tumors could receive immunotherapy as first-line therapy. Also, patients with wild-type *RAS* and *BRAF* tumors, HER2-amplification, and are not appropriate for intensive therapy can receive HER2 inhibitor therapy. Once these factors are known, the selection of the appropriate regimen is based on the toxicity profile and convenience of administration for the patient. Based on the comparable results of FOLFIRI versus FOLFOX, either of these regimens is considered the reference standard in metastatic colorectal cancer. Most patients will receive first- and second-line regimens and patient preference for either sequence of treatments based on their different toxicity profiles is important. FOLFIRI may be chosen initially in patients with preexisting neuropathies, whereas FOLFOX may be chosen in patients with increased bilirubin or known UGT1A1 deficiency (known risk factors for delayed diarrhea). Alopecia occurs much more frequently with irinotecan compared to oxaliplatin combinations. Because FOLFOX can cause persistent neuropathy, a rationale for starting with FOLFIRI is that time-to-progression is longer with first-line treatment than in second line. Therefore, the time to death during which some patients will have to live with neuropathy may be shorter. Capecitabine is an appropriate substitute for IV fluorouracil in oxaliplatin combination regimens. Because of a higher response rate and modest survival benefit with FOLFOXIRI, this four-drug combination may be useful for patients with initially aggressive and symptomatic disease. Select patients who are candidates for FOLFOXIRI may benefit from the addition of bevacizumab, but the incidence of moderate or severe toxicities is increased.

Metastatic Disease: Second-Line and Subsequent Therapy

Systemic chemotherapy represents the mainstay of therapy for patients who have progressive disease following initial treatment for metastatic disease. Table 153-7 lists treatment options for relapsed/refractory metastatic disease.[44,45] Treatment options are based on the type of and response to prior treatments, the site and extent of disease, and patient factors and treatment preferences.

TABLE 153-7

Second-Line and Salvage Chemotherapy Regimens for Metastatic Colorectal Cancer

Disease Progression with First-Line Regimen	Comments
Second-line options	
FOLFIRI or irinotecan	After previous oxaliplatin-based regimen (without irinotecan) (ie, FOLFOX, CAPEOX); use with caution in patients with elevated bilirubin
FOLFIRI + bevacizumab or ziv-afilbercept or ramucirumab	After previous oxaliplatin-based regimen (without irinotecan) (ie, FOLFOX, CAPEOX); use with caution in patients with elevated bilirubin; bevacizumab is preferred antiangiogenic agent based on toxicity and cost
FOLFOX or CAPEOX ± bevacizumab	After previous irinotecan-based regimen (without oxaliplatin) (ie, FOLFIRI); bevacizumab FDA-approved to continue with second-line options
FOLFOX + cetuximab or panitumumab	After previous irinotecan-based regimen (without oxaliplatin) (ie, FOLFIRI); only if *RAS* wild-type and *BRAF* wild-type
Irinotecan + bevacizumab or ziv-afilbercept or ramucirumab	After previous oxaliplatin-based regimen (without irinotecan) (ie, FOLFOX, CAPEOX); use with caution in patients with elevated bilirubin; bevacizumab is preferred antiangiogenic agent based on toxicity and cost
FOLFIRI + cetuximab or panitumumab	After previous oxaliplatin-based regimen (without irinotecan) (ie, FOLFOX, CAPEOX); only if *RAS* wild-type and *BRAF* wild-type; if neither previously given; use with caution in patients with elevated bilirubin
Irinotecan ± cetuximab or panitumumab	Only if *RAS* wild-type and *BRAF* wild-type; if neither previously given; use with caution in patients with elevated bilirubin
Encorafenib + (cetuximab or panitumumab)	Only if *BRAF V600E* mutation positive
Nivolumab ± ipilimumab	Only if dMMR/MSI-H
Dostarlimab	Only if dMMR/MSI-H
Pembrolizumab	Only if dMMR/MSI-H
Trastuzumab + (pertuzumab or lapatinib) or fam-trastuzumab deruxtecan-nxki	Only if *HER2*-amplified and *RAS* and *BRAF* wild-type
Therapy After Second Progression or Third Progression (can use any of the previous recommendations)	
Regorafenib	Used after progressed through all available regimens
Trifluridine/tipiracil ± bevacizumab	Used after progressed through all available regimens
Clinical trial	If available and only if patient eligible
Best supportive care	Appropriate for patients who do not want to pursue treatment, or not eligible for cancer-directed therapy, or if quality of life is expected to decrease

CAPEOX, capecitabine plus oxaliplatin; dMMR, DNA mismatch repair deficiency; FOLFIRI, fluorouracil plus leucovorin plus irinotecan; FOLFOX, fluorouracil plus leucovorin plus oxaliplatin; MSI-H, high microsatellite instability.

Data from References 44,45.

Systemic Chemotherapy

On disease progression following standard initial therapy, appropriate treatment options depend primarily on the type of prior therapy received (see Table 153-7). Because most patients will have received a combination of a fluoropyrimidine with either irinotecan or oxaliplatin, second-line therapy with the alternate regimen should be considered. Patient survival can exceed 2 years with this approach and it is important for patients to receive all traditional chemotherapy options if possible. Targeted agents can either be added to the regimens or used as single agents.

Irinotecan

Irinotecan improves overall survival as compared to either best supportive care or continuous-infusion fluorouracil in patients who had progressed within 6 months of treatment with fluorouracil.[44] However, this approach is rarely used since single-agent fluorouracil is rarely given as first-line therapy.

The use of the FOLFIRI regimen after progression with first-line FOLFOX demonstrated an objective response rate of 4% with a median progression-free survival of 2.5 months.[44] These results are consistent with observations that demonstrate improved outcomes in those patients who are able to receive all active cytotoxic agents during the course of their disease.

Based on these results, irinotecan-based therapy should be considered standard second-line therapy for patients with disease progression with first-line treatment with oxaliplatin-containing regimens. Continuous-infusion fluorouracil with leucovorin and irinotecan (FOLFIRI), with or without targeted therapy, is most commonly given.

Oxaliplatin

Oxaliplatin plus fluorouracil and leucovorin should be considered for patients who received primary treatment with irinotecan plus fluorouracil.[44] The combination of oxaliplatin plus fluorouracil and leucovorin is also effective as salvage therapy after initial treatment with irinotecan plus fluorouracil and leucovorin, with a similar response rate. Although irinotecan can be used effectively as a single agent in colorectal cancer, it should be noted that oxaliplatin does not have substantial activity alone, and should only be given in combination regimens.

Trifluridine/Tipiracil

Trifluridine is a thymidine-based nucleoside analog that is incorporated into DNA and inhibits cell proliferation. The addition of tipiracil increases trifluridine exposure by inhibiting its metabolism by thymidine phosphorylase. This combination chemotherapy product has activity in both *RAS* mutant and wild-type tumors. Trifluridine/tipiracil is FDA approved for treatment of metastatic colorectal cancer patients who have been previously treated with an fluoropyrimidine-, oxaliplatin-, and irinotecan-containing regimens, an anti-VEGF targeted therapy, and an anti-EGFR monoclonal antibody if *RAS* wild-type.[74] Trifluridine/tipiracil improves overall survival by approximately 2 months. This chemotherapy product is administered 35 mg/m^2 orally twice daily within 1 hour of completing morning and evening meals on days 1 through 5 and days 8 through 12 of a 28-day cycle. Common adverse drug reactions include myelosuppression, fatigue, diarrhea, nausea/vomiting, abdominal pain, and pyrexia.

Targeted Therapy

The addition of targeted therapy to chemotherapy in second and subsequent therapies does improve outcomes, but typically also increases toxicity. EGFR inhibitors may be administered in combination with other regimens in second-line and subsequent therapies. Angiogenesis inhibitors can also be used in second-line and subsequent therapy in combination with other regimens, even when they were used in first-line therapy.

EGFR Inhibitors

9 Patients with wild-type *RAS* and wild-type *BRAF* tumors who experience progression on therapies that do not contain an EGFR inhibitor may benefit from the combination of cetuximab or panitumumab and irinotecan, FOLFOX, or FOLFIRI.[44] However, further treatment is not recommended in those who had progressed while receiving an EGFR inhibitor. The combination of cetuximab and irinotecan significantly improves response rates (16% vs 4%) and progression-free survival (4 vs 2.6 months), but not overall survival when compared with irinotecan alone.[75] Panitumumab in combination with FOLFIRI also improves response rates (35% vs 10%) and progression-free survival (5.9 vs 3.9 months), but did not improve overall survival.[76]

BRAF Inhibitors

In patients with *BRAF V600E* mutations, a two-drug regimen of encorafenib (a BRAF inhibitor) and an EGFR inhibitor (cetuximab or panitumumab) is recommended to improve overall outcomes in second- and subsequent-line therapies for metastatic disease. This regimen produces overall response rates of 20% and a median overall survival time of 9.3 months.[77] The most common adverse drug reactions with this doublet regimen are acneiform rashes and diarrhea.

Angiogenesis Inhibitors

Angiogenesis inhibitors including VEGF inhibitors bevacizumab, ramucirumab, and ziv-aflibercept and the multikinase inhibitor regorafenib may be used in patients who have progressed on other therapies (see Table 153-7). VEGF inhibitors may be used as second- or subsequent-line therapies, whereas regorafenib is indicated for to third- or subsequent-line use. The NCCN guidelines recommend bevacizumab over ramucirumab and ziv-aflibercept based on toxicity and cost. Continuation of bevacizumab as second-line therapy provides a modest improvement in overall survival based on several clinical trials.[44] Bevacizumab may also be added to another second-line therapy in patients who did not receive it as part of their initial therapy, also resulting in a modest improvement in overall survival (12.1 vs 10.8 months).[78] Single-agent bevacizumab is not recommended because it is inferior to combination therapy.[44]

Ziv-aflibercept is a soluble recombinant fusion protein designed to block the angiogenic process. The agent was developed by fusing sections of the VEGFR-1 and VEGFR-2 immunoglobulin domains to the F_c portion of human immunoglobulin G1 and blocks VEGF-A, VEGF-B, and placental growth factor (PIGF) by "trapping" the ligands before they get to the native transmembrane receptors. In a phase III randomized trial, FOLFIRI plus ziv-aflibercept modestly, but significantly improves overall survival (13.5 vs 12.1 months) compared to FOLFIRI after progression on an oxaliplatin-based regimen.[79] It is dosed at 4 mg/kg as an IV infusion over 1 hour every 2 weeks and is associated with similar adverse drug reactions as bevacizumab.

Ramucirumab is a human monoclonal antibody that binds directly to the ligand-binding pocket of VEGFR-2 to block binding of VEGF-A, VEGF-C, and VEGF-D. A phase III randomized placebo-controlled trial of patients who progressed on an oxaliplatin-based regimen and bevacizumab were randomized to receive FOLFIRI with or without ramucirumab.[80] A modest but significant improvement in overall survival (13.3 vs 11.7 months) and progression-free survival (5.7 vs 4.5 months) were observed. Ramucirumab is administered as 8 mg/kg IV over 1 hour every 2 weeks and is associated with similar adverse drug reactions as bevacizumab.

The addition of ziv-aflibercept or ramucirumab to oxaliplatin regimens has not been evaluated and therefore is not recommended.[44] Additionally, the use of either of these drugs following failure of a bevacizumab-containing regimen has not been evaluated. Therefore, ziv-aflibercept and ramucirumab should only be used in patients naïve to antiangiogenic regimens and only with irinotecan-containing regimens.

Regorafenib, a small-molecule inhibitor of tumor angiogenesis (VEGFR-1, VEGFR-2, and VEGFR-3) and other downstream targets (FGF receptors, PDGF receptors, BRAF, KIT, and RET), is approved for the third- or fourth-line treatment of metastatic colorectal cancer. This oral agent is dosed 160 mg once daily for the first 21 days of each 28-day cycle, although it is common to start at a lower dose (80 or 120 mg) and titrate as tolerated.[44] In a phase III trial of patients with metastatic colorectal cancer and progression during or within 3 months of last chemotherapy, regorafenib demonstrated a 1.4-month improvement in overall survival when compared to placebo.[81] Patients with mutant or wild-type *RAS* may receive this therapy. Because this is an oral-only regimen, patients must be counseled on its use and potential toxicity. Regorafenib should be taken with a low-fat breakfast and may interact with CYP450 3A4 inducers and inhibitors. Toxicities include hypertension, hand-foot syndrome, diarrhea, and hepatotoxicity.

HER2 Inhibitors

HER2, a member of the same kinase family as EGFR, is rarely overexpressed in colorectal cancer.[44] However, *HER2* overexpression/amplification is more common in *RAS* and *BRAF* wild-type tumors. MyPathway, a basket trial, showed that in patients with HER2 amplified metastatic colorectal cancer, the combination of trastuzumab and pertuzumab (HER2 monoclonal antibodies) produced response rates of 32%.[82] The most common adverse drug reactions are diarrhea, fatigue, and nausea. According to HERACLES study, trastuzumab and lapatinib (a *HER2* inhibitor) in treatment of refractory colorectal cancer patients with *RAS* wild-type produced responses in patients who typically are refractory to therapy, producing a 30% response rate.[83] Adverse drug reactions of *HER2* inhibitors include fatigue, skin rash, and bilirubin increases.[82] *HER2* inhibitor therapy can be an option for those with tumor *HER2* overexpression when other options have failed.

Immunotherapy

⑩ Pembrolizumab, a humanized, IgG4 monoclonal antibody that binds to programmed cell death ligand-1, or PD-L1, with high affinity, is effective in metastatic colorectal cancer with dMMR or high tumor mutational burden When used as first-line therapy in patients with metastatic colorectal cancer with dMMR, pembrolizumab has improved response rates and progression-free survival times compared with chemotherapy.[84] Nivolumab, another humanized IgG4 monoclonal antibody PD-1 inhibitor, has also been evaluated with or without ipilimumab in patients with metastatic colorectal cancer who have dMMR/MSI-H tumors. As first-line therapy, nivolumab and ipilimumab also improve response rates and progression-free survival times compared with chemotherapy alone.[85] Immunotherapy (dostarlimab, pembrolizumab, nivolumab +/- ipilimumab) may also be used as subsequent-line therapy if patients who have not previously received immunotherapy.

Immune checkpoint inhibitors are generally well tolerated. The adverse drug reactions are typically immune-mediated and commonly affect the skin, liver, kidneys, gastrointestinal tract, lung, and endocrine systems. Immune-mediated pneumonitis is an uncommon but serious adverse drug reactions. Close monitoring for these adverse drug reactions is important to allow for prompt identification and treatment to minimize morbidity and mortality. Treatment includes temporary treatment suspension and corticosteroid treatment. Refractory cases may require infliximab or immunotherapies.[86]

EVALUATION OF THERAPEUTIC OUTCOMES

The goal of monitoring is to either evaluate whether the patient is receiving any benefit from the management of the disease or to detect recurrence for those who have completed curative intent therapy. During treatment for active disease, patients should undergo monitoring for measurable tumor response, progression, or new metastases; these tests may include chest, abdominal or pelvic CT scans, or other imaging modalities, depending on known sites of disease and previous imaging results, and CEA measurements every 3 months if the CEA is or was previously elevated. These radiologic tests and other selected laboratories should also be evaluated with the development of any new symptoms or significant change in disease status. Patients should be evaluated during every treatment visit for the presence of anticipated adverse drug reactions, which generally include loose stools or diarrhea, nausea or vomiting, mouth sores, fatigue, and fever, as well as other adverse drug reactions such as neuropathy (oxaliplatin) and skin rash (EGFR inhibitors). In addition, a complete blood cell count should be obtained prior to each course of chemotherapy administration to ensure that hematologic indices are adequate. Baseline liver function tests and an assessment of renal function should be evaluated prior to and periodically during therapy. Hepatotoxicity may be seen with regorafenib, and in addition to neuropathy, oxaliplatin may cause renal injury. Serum electrolytes, including magnesium, should be monitored during treatment with EGFR inhibitors. Patients receiving bevacizumab, ziv-aflibercept, or regorafenib should be evaluated for hypertension and proteinuria.

Symptoms of recurrence such as pain syndromes, changes in bowel habits, rectal or vaginal bleeding, pelvic masses, anorexia, and weight loss develop in less than 50% of patients. Recurrences can be detected in asymptomatic patients because of increased serum CEA levels that lead to further examination. Although the value of CEA monitoring for disease recurrence is controversial because of its cost and emotional stress associated with false-positive elevations, CEA monitoring plays an important role in postoperative follow-up studies. A PET scan can identify sites of metastatic disease when a rising CEA level suggests metastatic disease but CT scans and other imaging studies are negative.

Patients who undergo curative surgical resection, with or without adjuvant therapy, require close follow-up based on the premise that early detection and treatment of recurrence could still render them cured. In addition, early treatment for asymptomatic metastatic colorectal cancer appears to be superior to delayed therapy. Specific practice guidelines for postoperative surveillance examinations following successful treatment for stage II or III disease were developed by NCCN and include history, physical examination, and CEA test every 3 to 6 months for the first 2 years, then every 6 months for a total of 5 years; chest and abdominal and pelvic CT scans every 6 to 12 months for up to 5 years following primary therapy; and colonoscopy at about 1 year after surgery. If an obstructing lesion prevented preoperative colonoscopy, it should be done within 3 to 6 months. Repeat colonoscopies are recommended at 3 years, unless findings of polyps warrant closer follow-up. PET/CT is not routinely indicated. Less intensive surveillance is recommended for patients treated for stage I disease because of low risk of recurrence.[44]

Posttreatment surveillance should also include a survivorship care plan with immunizations for vaccine-preventable diseases, early detection of second primary cancers, and support systems that encourage smoking cessation, establish regular exercise and maintain a healthy BMI, and encourage healthy lifestyle and dietary choices.[44] In addition, if there is a strong family history of colorectal cancer or related malignancies or clinicopathologic findings in an individual consistent with a hereditary syndrome, a consultation with a genetic counselor is indicated. Advances in the treatment for colorectal cancer now offer the potential to improve patient survival, but for many patients, improved disease-free and progression-free survival represent equally important therapeutic outcomes. Although treatment approaches for metastatic colorectal cancer have been historically assessed by their ability to produce a measurable objective tumor response, which is generally believed necessary for any treatment to improve survival, the effects of therapies on survival are clinically more meaningful than their ability to induce a tumor response. However, with the availability of multiple active treatments for metastatic disease, and the likelihood that patients will receive more than one during the course of their treatment, improvements in overall survival with new therapies will be increasingly difficult to determine.

In the absence of the ability of a specific treatment to demonstrate improved overall survival, important outcome measures should include the effects of the treatment on patient symptoms, daily activities, performance status and other quality-of-life indicators, progression-free survival, and time-to-treatment failure. Because most metastatic colorectal cancers are incurable, a specific decision regarding an individual patient's care will ultimately be required. This decision should be based on a careful assessment of the balance between risks associated with treatment (or lack thereof) and benefits of treatment. Efforts should also be made to ensure that the costs of screening, diagnostic tests, treatments, and procedures for colorectal cancer are consistent with their value in improving patient outcomes.

CONCLUSION

Colorectal cancer is a common cancer diagnosed in adults, but can be detected early through routine screening starting at the age of 45 years. Early-stage cancers can be cured with surgery. The addition of chemotherapy with a fluropyrmdine-based regimen in some individuals with stage II and all individuals with stage III colorectal cancer is recommended following surgery to improve outcomes. In patients with rectal cancer, neoadjuvant chemotherapy and chemosensitized XRT followed by surgery is recommended to decrease the likelihood of recurrence. In patients with advanced colorectal cancer, chemotherapy is palliative and all active cytotoxic agents are administered to improve survival. The addition of targeted therapy in subsequent-line treatments is beneficial and depends upon specific patient factors. Unlike some other solid tumors, immunotherapy is only beneficial in a small subset of patients, but the benefit can be substantial in eligible patients.

ABBREVIATIONS

APC	adenomatous polyposis coli (gene)
BMI	body mass index
CAPEOX	capecitabine plus oxaliplatin
CEA	carcinoembryonic antigen
CI	confidence interval
CIN	chromosomal instability
CIMP	CpG island methylator phenotype

COX-2	cyclooxygenase-2
CT	computed tomography
DPD	dihydropyrimidine dehydrogenase
EGFR	epidermal growth factor receptor
EpCAM	epithelial cell adhesion molecule
FAP	familial adenomatous polyposis
FDA	Food and Drug Administration
FIT	fecal immunochemical test
FOBT	fecal occult blood test
FOLFIRI	fluorouracil, leucovorin, and irinotecan
FOLFOX	fluorouracil, leucovorin, and oxaliplatin
FOLFOXIRI	fluorouracil and leucovorin, oxaliplatin, irinotecan
FSIG	flexible sigmoidoscopy
gFOBT	guaiac-based fecal occult blood test
HDI	human development index
HR	hazard ratio
LOH	loss of heterozygosity
MAPK	mitogen-activated protein kinase
MMR	mismatch-repair
MRI	magnetic resonance imaging
MSI	microsatellite instability
mt-sDNA	multi-target stool DNA
NCCN	National Comprehensive Cancer Network
NSAID	non-steroidal anti-inflammatory drug
PD-1	programmed cell death protein
PD-L2	programmed cell death ligand-2

PET	positron emission tomography
PI3K	phosphatidylinositol 3-kinase
TGF-β	transforming growth factor-β
TS	thymidylate synthase
UGT1A1	uridine diphosphate-glucuronosyltransferase
USPSTF	United States Preventive Services Task Force
VEGF	vascular endothelial growth factor
VEGFR	vascular endothelial growth factor receptor
XELOX	capecitabine plus oxaliplatin
XRT	radiation therapy

SELF-ASSESSMENT QUESTIONS

1. Which of the following factors is associated with an increased risk of developing colorectal cancer?

   A. High dietary caffeine intake

   B. Rectal hemorrhoids

   C. Gastroesophageal reflux disease

   D. Chronic ulcerative colitis

2. A 30-year-old healthy individual has a father and paternal grandfather who were diagnosed with colon cancer. The individual would like to know what to take to prevent colon cancer. Which of the following recommendations is *most* appropriate?

   A. No preventative therapy is recommended in colon cancer.

   B. Take calcium (1,000 mg) and vitamin D (400 international units) orally each day.

   C. Take a low dose of aspirin (81-160 mg) orally each day.

   D. Take celecoxib (100 mg) orally twice daily.

3. At what age should routine colorectal cancer screening begin for an individual with average risk?

   A. 40 years

   B. 45 years

   C. 50 years

   D. 55 years

4. A 58-year-old White individual is diagnosed with stage III rectal cancer. Which of the following is the most appropriate treatment?

   A. Surgery followed by adjuvant FOLFOX

   B. Neoadjuvant chemoradiation followed by surgery followed by adjuvant chemotherapy with FOLFOX

C. Neoadjuvant chemoradiation therapy followed by surgery

D. FOLFOX × 6 months alone

5. Which of the following colorectal cancer screening methods is *most* appropriate for a 55-year-old individual that refuses to take a bowel prep as part of the procedure?

A. Virtual (CT) colonoscopy every 10 years

B. Annual digital rectal exam

C. Annual FIT

D. mt-sDNA every 5 years

6. A 53-year-old individual with stage II hypertension is diagnosed with Stage IIB colon cancer following a routine screening colonoscopy. A surgical resection of the mass and regional mesenteric lymph nodes was performed. The tumor was poorly differentiated and showed evidence of lymphatic invasion. Which of the following statements regarding adjuvant chemotherapy for this individual is true? Adjuvant chemotherapy:

A. does not benefit patients with stage II colon cancer; should not receive additional treatment.

B. should be offered because this cancer is associated with several poor prognostic factors.

C. is standard of care for stage II colon cancer; should receive treatment.

D. is contraindicated in patients with hypertension; should not receive additional treatment.

7. Which of the following adjuvant treatment regimens for stage III colon cancer is most appropriate? Postoperative:

A. XRT

B. FOLFOX (fluorouracil, leucovorin, oxaliplatin) chemotherapy

C. Regorafenib

D. Pembrolizumab

8. A 67-year-old individual is diagnosed with stage IV cancer of the colon with several liver and lung metastases. Capecitabine chemotherapy will be initiated. What is the goal of chemotherapy in this individual?

A. Shrink the disease so that surgery can be performed to remove the tumors

B. Eradicate potential micrometastases after surgical resection

C. Provide symptom control only

D. Reduce symptoms, avoid disease-related complications, and prolong survival

9. A 62-year-old individual with a history of type 2 diabetes mellitus and peripheral neuropathy is diagnosed with inoperable metastatic colon cancer. The oncologist has suggested the combination of infusional fluorouracil, leucovorin, and irinotecan (FOLFIRI) as an initial regimen instead of an oxaliplatin-containing regimen based on the treatment toxicity profile. What adverse drug effect should be minimized with FOLFIRI?

A. Diarrhea

B. Myelosuppression

C. Neuropathy

D. Mucositis

10. A 68-year-old individual with a history of hypertension was diagnosed with stage IV colorectal cancer. The tumor was *KRAS* mutant and EGFR positive. His blood pressure is controlled with medications. Which of the following initial treatment regimens is *most* appropriate?

A. FOLFOX plus bevacizumab

B. FOLFOX plus cetuximab

C. Capecitabine plus oxaliplatin plus ziv-aflibercept

D. FOLFOXIRI plus cetuximab

11. A 61-year-old individual with *KRAS*-mutated and MSI-high metastatic colon cancer was initially treated with FOLFOX. After 6 months of chemotherapy, they experienced a partial response to treatment and therapy was continued. Four months later, worsening abdominal pain developed and an abdominal CT scan showed new sites of disease in the liver. The treatment regimen was changed to FOLFIRI. Two months later, imaging studies show an increase in the size and number of liver metastases. Which of the following modifications to the current treatment regimen is now *most* appropriate?

A. Discontinue current regimen; start pembrolizumab

B. Continue FOLFIRI and add bevacizumab

C. Continue FOLFIRI; discontinue bevacizumab; start ziv-aflibercept

D. Discontinue current regimen; start FOLFOXIRI plus panitumumab

12. An adult patient is diagnosed with metastatic right-sided colorectal cancer, *KRAS* wild-type and is suitable for intensive therapy. Which of the following would be an appropriate regimen?

A. FOLFOX plus bevacizumab

B. FOLFOX plus cetuximab

C. Cetuximab

D. Regorafenib

13. An adult individual with metastatic colorectal cancer is considered for initial systemic chemotherapy. Genoytping as part of the pretreatment evaluation shows a homozygous UGT1A1*28. Based on the results of this test, how might the treatment plan be adjusted?

A. Capecitabine might be preferred to fluorouracil in this therapy.

B. Paitent might not be a candidate for oxaliplatin.

C. The initial dose of irinotecan might need to be adjusted.

D. Bevacizumab might be indicated as part of this therapy.

14. A 60-year-old individual is to receive cetuximab plus irinotecan for metastatic colorectal cancer that progressed with irinotecan, fluorouracil, and leucovorin chemotherapy. Previous chemotherapy was well tolerated, with only minor nausea and occasional loose stools. Which of the following counseling points is *most* appropriate with regard to this new chemotherapy regimen?

A. Infusion-related reactions with cetuximab are common.

B. Dose-limiting diarrhea is the most frequent complication with this regimen.

C. Cetuximab is associated with a papulopustular skin rash.

D. Peripheral neuropathy associated with this regimen is often dose-limiting.

15. A 61-year-old adult underwent surgical resection 8 months ago for stage III colon cancer. Six months of postoperative treatment with weekly fluorouracil plus leucovorin was administered. Routine follow-up imaging and laboratory tests confirmed cancer recurrence in the liver and lungs. Otherwise patient is asymptomatic and healthy and is now about to start the FOLFOX regimen (oxaliplatin, fluorouracil, and leucovorin). Which of the following patient counseling points is *most* appropriate for this regimen?

A. Avoid cold drinks and use of ice and cover skin before exposure to cold or cold objects the day before, day of and up to 2 days after chemotherapy.

B. If diarrhea begins after chemotherapy, begin atropine 4 mg po then 2 mg every 2 hours until symptom-free for 12 hours.

C. Eat a low-fat diet throughout chemotherapy.

D. Contact your physician immediately if you experience abdominal pain with vomiting or constipation.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Inflammatory bowel disease such as ulcerative colitis has a twofold greater risk of developing colorectal cancer compared with average-risk individual. See "Etiology and Risk Factors" section for more information on this and other risk factors.

2. **A.** Physical inactivity and elevated BMI are associated with an elevated risk of colon adenoma, colon cancer, and rectal cancer. Although tobacco use is associated with an increased risk of colon cancer, supplementation with folic acid and vitamin D has not been proven to be beneficial. Daily aspirin is limited to individuals in whom the benefit outweighs the risk. Dairy products have not been associated with an increased risk of colorectal cancer. High consumption of red and processed meat is associated with an increased colon cancer risk and a diet high in fiber such as fruit, vegetables and grain is associated with a lower risk. See "Lifestyle Factors" section for more information on this and other factors.

3. **B.** The age to begin colorectal cancer screening for the average-risk individual is 45 years. This is a relatively new change in guidelines based on the increasing incidence of colorectal cancer in adults younger than 50 years. Recommended programs for regular screening include a colonoscopy every 10 years, annually with a high-sensitivity gFOBT or FIT, or an FSIG every 5 years or every 10 years along with FIT every 1-2 years. See "Screening" section for more information.

4. **B.** Combined-modality therapy consisting of chemoradiation and fluoropyrimidine-based chemotherapy perioperatively for a total of 6 months is the treatment for stage II and III rectal cancers. Most commonly, neoadjuvant (preoperative) chemoradiation followed by surgery and adjuvant (postoperative) chemotherapy or total neoadjuvant therapy (fluoropyrimidine-based chemotherapy followed by chemo XRT [or vice versa] followed by surgery) are used. FOLFOX or CAPEOX are the preferred fluoropyrimidine-based chemotherapy regimens used. FOLFOX × 6 months is the standard treatment for stage III colon cancer. See "Treatment; Adjuvant and Neoadjuvant Therapy for Rectal Cancer" section for more information.

5. **C.** An annual FIT is noninvasive and does not involve a bowel preparation. It is recommended as an option for colorectal cancer screening. Multi-targeted stool DNA is also an option that does not require a bowel preparation but the recommended interval for colorectal screening is every 1-3 years. Although a virtual colonoscopy is not invasive, it still requires a bowel preparation to clear out the colon for viewing and is recommended at an interval of every 5 years. Finally, a digital rectal examination is not recommended for CRC screening. See "Prevention and Screening" (Screening) section for more information.

6. **B.** Patients with stage II disease at high risk for relapse should be offered adjuvant chemotherapy. High-risk features include those patients with inadequate lymph node sampling, perforation of the bowel at presentation, poorly differentiated tumors, lymphovascular invasion, perineural invasion, inadequately sampled lymph nodes (<12 evaluated), T_4 lesions (stage IIB/IIC), and lesions with localized perforation or close or indeterminate margins. This patient has lymphatic invasion which is a risk factor and would benefit from adjuvant chemotherapy. See "Treatment" (Operable Disease; Adjuvant Chemotherapy for Colon Cancer) section for more information.

7. **B.** FOLFOX (fluorouracil/leucovorin and oxaliplatin) is a preferred regimen for patients with stage III colon cancer who can tolerate combination

therapy according to the NCCN guidelines. Alternatives are capecitabine + oxaliplatin, capecitabine alone, or fluorouracil/leucovorin. Neoadjuvant XRT may be used in a small group of patients (eg, those with T4 tumors adfixed to other structures), although it is most commonly given in combination with chemotherapy. Regorafenib and pembrolizumab are used in metastatic colon cancer. See "Treatment" (Operable Disease; Adjuvant Chemotherapy for Colon Cancer) section for more information.

8. **D.** In patients with metastatic (stage IV) colorectal cancer, the goal of therapy is to reduce symptoms, avoid disease-related complications, and prolong survival. Treatment goals for cancer of the colon or rectum are based on the stage of disease at presentation. Stages I, II, and III disease are considered potentially curable and the goal of management is to eradicate potential micrometastases after surgical resection. Most patients with stage IV disease are not curable, and treatments for metastatic disease are considered palliative to reduce symptoms, avoid disease-related complications, and prolong survival. However, special attention should be given to those with oligometastatic lesions in the liver or lung since potential cure is still possible for some of these patients. See "Treatment: Desired Outcomes" section for more information.

9. **C.** Neuropathy is associated with oxaliplatin and the FOLFIRI regimen does not contain oxaliplatin. Diarrhea (both acute and late) and mucositis can occur with irinotecan and also with fluorouracil. Myelosuppression tends to be more common/severe with FOLFIRI than with oxaliplatin-containing regimens. See "Treatment" (Operable Disease; Fluorouracil Plus Oxaliplatin Regimens; Metastatic Disease: Initial Therapy; Unresectable Metastatic Colorectal Cancer) section for more information.

10. **A.** First-line treatment of *RAS* mutated metastatic colorectal cancer includes a fluorouracil-based regimen +/- bevacizumab. Although this patient has EGFR positive disease, and EGFR inhibitor, such as cetuximab, is not indicated. EGFR inhibitors are only appropriate when *RAS* and *BRAF* wild-type disease is present. Ziv-aflibercept is only indicated for progression after other therapies. See Table 153-6 and "Treatment" (Metastatic Disease: Initial Therapy; Unresectable Metastatic Colorectal Cancer) section for more information.

11. **A.** When progression occurs during a regimen for metastatic colorectal cancer, the regimen is always discontinued and a new one is initiated. Patients with metastatic colorectal cancer and high microsatellite instability receive benefit from immunotherapy after disease progressions. Pembrolizumab, dostarlimab, nivolumab, and or the combination of nivolumab and ipilimumab may be used. See "Treatment" (Metastatic Disease: Initial Therapy; Unresectable Metastatic Colorectal Cancer; Immunotherapy) section and Table 153-6 for more information.

12. **A.** EGFR inhibitors (cetuximab, panitumumab) are appropriate when *RAS* and *BRAF* wild-type disease is present; however, those with right-sided tumors (cecum to hepatic flexure) do not have improved survival. Therefore, EGFR inhibitors are not recommended in patients with right-sided tumors and instead you would use same regimen as you might in those with mutations of *RAS* or *BRAF* (eg, FOLFOX + bevacizumab). Regorafenib is recommended as third- or fourth-line therapy. See "Treatment" (Metastatic Disease: Initial Therapy; Targeted Therapy) section for more information.

13. **C.** Patients with UGT1AI*28 genotype should be considered to receive a dose reduction of irinotecan because they are not able to glucuronidate irinotecan as effectively as those who do not have this genotype. The prolonged systemic exposure to irinotecan and its active metabolite SN-38 can result in severe delayed diarrhea. Therefore, dose adjustments are recommended to avoid this adverse drug reaction. See "Treatment" (Metastatic Disease: Initial Therapy; Unresectable Metastatic Colorectal Cancer; Chemotherapy) section for more information.

14. **C.** Cetuximab, an EGFR monoclonal antibody, is associated with a papulopustular skin rash that can be severe, requiring treatment, and in some cases dose reductions or interruptions. Infusion-related reactions can occur but are rare (3%). Neither dose-limiting diarrhea or neuropathy is common with cetuximab. See "Treatment" (Metastatic Disease: Initial Therapy; Targeted Therapy) section for more information.

15. **A.** Oxaliplatin can cause acute neuropathies, occur in about 90% of patients, and are precipitated or exacerbated by exposure to cold temperatures or cold objects. Thus, patients should be instructed to avoid cold drinks and use of ice, and to cover skin before exposure to cold or cold objects before, during, and for 2 days following chemotherapy. Irinotecan is associated with moderate-to-severe late diarrhea and high-dose loperamide is used to treat it. Regorafenib is taken with a low-fat breakfast. Because of the risk of gastrointestinal perforation with bevacizumab patients should be instructed to call immediately if signs such as abdominal pain with vomiting or constipation occur. See (Operable Disease; Adjuvant Chemotherapy for Colon Cancer; Metastatic Disease: Initial Therapy; Unresectable Metastatic Colorectal Cancer; Chemotherapy; and Targeted Therapy) sections for more information.

Chapter 154: Prostate Cancer

Daniel J. Crona; Amber B. Cipriani

KEY CONCEPTS

KEY CONCEPTS

① Prostate cancer is the most frequent cancer in men in the United States. The risk of prostate cancer is higher in those with increased age, Black individuals, and those with a family history of prostate cancer.

② Screening is not universally recommended and individuals should discuss with their provider about risks versus benefits of screening. Digital rectal examination (DRE) and prostate-specific antigen (PSA) may be incorporated into individualized screening plans.

③ The prognosis for patients with prostate cancer depends on the histologic grade, the tumor size, and the disease stage. More than 85% of patients with localized disease, but less than 1% of those with metastatic disease can be cured.

④ Androgen deprivation therapy (ADT) with a luteinizing hormone-releasing hormone (LHRH) agonist plus an antiandrogen should be used in addition to radiation therapy for patients with locally advanced prostate cancer to improve outcomes over radiation therapy alone.

⑤ Systemic therapy for nonmetastatic castration-naïve disease that has not been treated with ADT may include either orchiectomy, LHRH agonist with or without an antiandrogen, gonadotropin-releasing hormone (GnRH) antagonist, or observation.

⑥ In metastatic castration-naïve disease, the addition of the following therapies to ADT improves survival: docetaxel, abiraterone, enzalutamide, or apalutamide.

⑦ Prostate cancer that has progressed despite androgen deprivation is called castration-resistant prostate cancer. First-line treatment options for nonmetastatic castration-resistant prostate cancer include apalutamide, darolutamide, and enzalutamide.

⑧ In metastatic castration-resistant prostate cancer, first-line treatment options include docetaxel with prednisone, abiraterone with prednisone, and enzalutamide. ADT is continued in all cases.

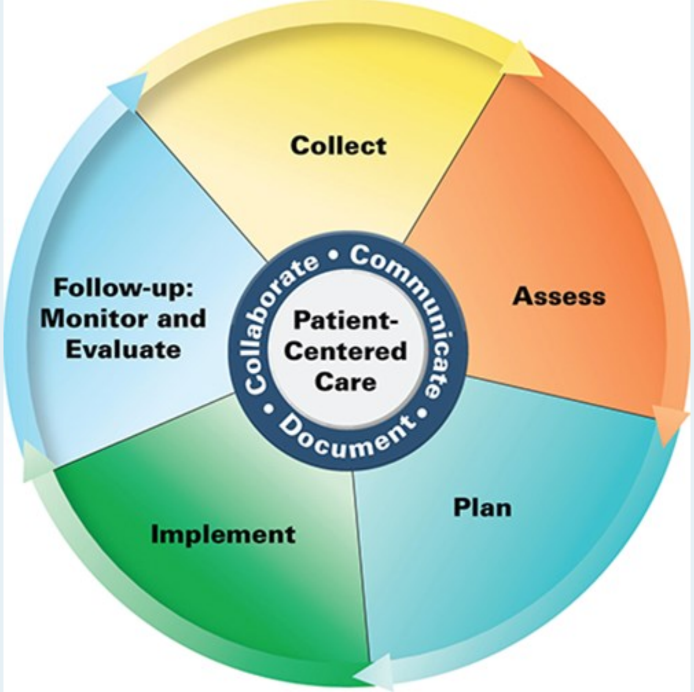
⑨ Germline genetic testing is recommended in patients with high-risk prostate cancer and/or a relevant family history. Somatic tumor genetic testing is recommended in metastatic disease to identify genetic variants that can be targeted with drug therapy.

⑩ Pembrolizumab may be considered in men whose tumors show deficiencies in deoxyribonucleic acid (DNA) mismatch repair (dMMR), test high for microsatellite instability (MSI-H), or have a tumor mutation burden greater than or equal to 10 mutations per megabase (TMB ≥ 10 mut/Mb).

⑪ Poly (ADP ribose) polymerase (PARP) inhibitors, including olaparib and rucaparib, can be considered in men with metastatic castration-resistant prostate cancer who have specific somatic or germline alterations in genes involved in homologous recombination (HR), such as *BRCA1* and *BRCA2*.

PATIENT CARE PROCESS

Patient Care Process for Prostate Cancer



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, race/ethnicity)
- Patient history (past medical, family, social, dietary habits)
- Family cancer history (to determine eligibility for and to interpret germline genetic testing)
- Current signs and symptoms (eg, frequency of urination, dribbling, hesitancy, pain, fatigue, weight loss, shortness of breath)
- Thorough medication history (including prescription, nonprescription medications, and other substances), drug allergies, and intolerances
- Objective data (see Table 154-3)
  - BP, heart rate, height, and weight
  - Labs (PSA level, complete blood count, serum electrolytes, renal function, liver function tests)
  - Physical examination (DRE, edema, breath sounds, ascites)
  - Imaging (see Table 154-3)
  - Pathology (Gleason score, determine number of positive biopsy cores)
  - Genetic testing (germline and/or somatic [tumor] based on risk factors)

Assess

- Determine the stage and risk category of disease based on, laboratory testing, imaging, and biopsy information (Table 154-4)
- Estimate life expectancy of the patient (can use Social Security Administration Life Insurance calculator)
- Evaluate current medication regimen and past medical history for potential drug-drug interactions or treatment contraindications
- Consider comorbidities that may impact therapy choice (cardiovascular risk, diabetes, seizure disorders)
- Address symptoms that require palliative management (ie, pain, impotence, fatigue, nausea)

- Identify concerns for medication access and medication adherence that could influence treatment choice
- Discuss short-term and long-term goals of care with the patient

Plan*

- Drug therapy regimen including drug(s), dose(s), route, frequency, and duration (see Table 154-7)
- Supportive care plan (antiemetics, premedication for chemotherapy, pain control, hot flash management)
- Monitoring parameters for adverse drug reactions (eg, complete blood count, liver function tests, subjective symptom assessments) and efficacy (eg, PSA levels, repeat imaging, symptom assessments)
- Patient education (self-monitoring for adverse drug reactions, expected timeframe for benefit and onset of adverse drug reactions, action needed for adverse drug reactions, monitoring schedule)
- Referrals to other providers when appropriate (eg, dietician, palliative care, urology)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Mitigate financial toxicity of drug therapy to ensure adherence
- Schedule follow-up

Follow-Up: Monitor and Evaluate

- Presence of adverse drug reactions
- Monitoring response to treatment (eg, PSA, imaging studies depending on location of disease)
- Patient adherence to the treatment plan using multiple sources of information
- Patient satisfaction with the treatment plan
- New comorbidities or medications that may impact the treatment plan and patient treatment goals

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Review the following case and answer the questions based on the information provided in the chapter:

A 60-year-old male presents to the ED with worsening back pain over the past 2 months. His lab reports were notable for a decreased hemoglobin of 10.1 g/dL (101 g/L; 6.27 mmol/L), a blood glucose of 280 mg/dL (15.5 mmol/L), and an alkaline phosphatase of 324 IU/L (5.4 µkat/L). A CT scan of the chest, abdomen, and pelvis revealed diffuse spine masses and bi-lateral rib masses suspicious for malignancy. A biopsy of a pelvic bone mass was consistent with prostate adenocarcinoma. Other relevant information is as follows:

- Past medical history: HTN, Afib, DM
- Family history: Father died of a myocardial infarction at the age of 57 years, mother died of breast cancer at the age of 47 years
- Medications: apixaban 5 mg BID, metoprolol 50 mg BID, nifedipine ER 60 mg daily, simvastatin 40 mg qHS, metformin 1,000 mg PO BID, empagliflozin 10 mg daily
- Vitals: BP 130/80, HR 81, Ht 176 cm, Wt 103.2 kg
- Lab reports:
  - PSA 132 ng/mL (mcg/L)
  - Testosterone 350 ng/dL (12.1 nmol/L)

Questions for self-assessment:

1. How would you classify this patient's prostate cancer? Describe if the cancer is metastatic or nonmetastatic and the castration status of the patient.
2. What treatment options are available to this patient to treat his cancer (based on your classification above)?
3. Perform a drug interaction screen for the available agents being considered to treat this patient's prostate cancer. Are there any contraindications? What changes to the patient's current medication regimen would you recommend if any of the agents were to be initiated (Hint: it might be helpful to make a table of the available options to treat prostate cancer and then consider these options with each of the drugs on the patient's current medication list).
4. Would this patient be eligible for genetic testing? (You can review the detailed recommendations for genetic testing in prostate cancer by accessing the current NCCN® Guidelines at: http://nccn.org)
5. Bonus question: Using resources outside of the chapter, suggest a possible cause of the patient's elevated alkaline phosphatase.

INTRODUCTION

In this chapter, the term "male" is used only to reflect the biological sex of individuals at birth and not the gender identified by the patient. Moreover, we recognize that not all patients with prostate cancer identify as "men" at the time of diagnosis and treatment of this condition. Prostate cancer is the most commonly diagnosed cancer in biological males in the United States.[1] For most, prostate cancer has an indolent course, and treatment options for early disease include expectant management, surgery, or radiation. With expectant management, patients are monitored for disease progression or development of symptoms. Localized prostate cancer can be cured by surgery or radiation therapy, but advanced and metastatic prostate cancers are not yet curable. Treatments for advanced and metastatic prostate cancers can provide significant disease palliation for many patients for several years after diagnosis. The endocrine dependence of this tumor is well documented, and hormonal manipulation aimed at decreasing circulating androgens remains the basis for the treatment of advanced and metastatic disease.

EPIDEMIOLOGY

① Prostate cancer is the most frequent cancer among biologically male individuals in the United States and represents the second leading cause of cancer-related deaths in biological males.[1] In the United States alone, it is estimated that 268,490 new cases of prostate cancer were diagnosed and more than 34,500 individuals died from this disease in 2022.[1] Although the incidence of prostate cancer increased during the late 1980s and early 1990s related to widespread PSA screening, the incidence declined rapidly from 2007 to 2014 because of recommendations against routine PSA screening. Deaths from prostate cancer have declined since 1993.[1]

The slowing decline in prostate cancer mortality between 2013 and 2019 is probably related to the decrease in PSA screening and an increase in advanced-stage diagnoses.[1]

ETIOLOGY

Table 154-1 summarizes the possible risk factors associated with prostate cancer.[2–4] The widely accepted risk factors for prostate cancer are age, race/ethnicity, and family history of prostate cancer. The disease is rare in those younger than 40 years, but the incidence sharply increases with each subsequent decade of life. The increased risk can likely be attributed to cumulative lifetime exposure to testosterone, which is a known growth signal for the prostate.

TABLE 154-1

Risk Factors Associated with Prostate Cancer

Factor	Possible Relationship
Probable Risk Factors	
Age	Greater than 70% of cases are diagnosed in men older than 65 years
Race/Ethnicity	Black individuals in the United States have a higher incidence and death rate
Genetic	Familial prostate cancer inherited in an autosomal dominant manner
	Germline mutations in *ATM, ATR, BRCA1, BRCA2, BRIP1, CHEK2, FAM175A, FH, GEN1, HOXB13, MRE11A, MSH2, MSH6, NBN, PALB2, PMS2, RAD51C,* or *RAD51D* are more common in metastatic/high-risk prostate cancer compared to localized/low-risk
	Inherited polymorphisms (eg, CAG repeat length) that lead to increased androgen receptor (AR) activation
Possible Risk Factors	
Environmental	Incidence varies worldwide
	Nationalized individuals adopt intermediate incidence rates between those of the US and their native country
Occupational	Increased risk associated with cadmium exposure
Diet	Mediterranean diet associated with reduced risk
	Increased risk associated with high-meat and high-fat diets
	Decreased intake of 25-dihydroxyvitamin D, lycopene, and β-carotene increases risk

Race and Ethnicity

The incidence of clinical prostate cancer varies across geographic regions. Scandinavian countries and the United States report the highest incidence of prostate cancer, while the disease is relatively rare in Japan and other Asian countries.[5] Black individuals in the United States have the highest rate of prostate cancer in the world, and prostate cancer mortality among them is more than twice that seen in White populations in the United States.[1] Hormonal, dietary, and genetic differences, and differences in access to healthcare may contribute to the altered susceptibility to prostate cancer in these populations.[2,3]

In addition, genetic variations in the androgen receptor gene *(AR)* exist. *AR* activation is inversely associated with CAG trinucleotide repeat length. Under normal circumstances, a CAG trinucleotide, consisting of the DNA building blocks cytosine, adenine and guanine, is repeated 10 to 35 times within a given gene. However, shorter CAG repeat sequences in *AR* have been found in Black individuals, and a meta-analysis demonstrated that carriers of a short CAG repeat had a 20% increased risk of prostate cancer when compared to individuals with long CAG repeats.[2]

Genetics and Family History

Approximately 5% to 10% of prostate cancers are believed to be inherited, but individuals with a brother or father with prostate cancer have twice the risk for developing prostate than the rest of the population.[6] Familial clustering of prostate cancer syndrome has been reported, and genome-wide scans have identified potential prostate cancer susceptibility candidate genes. Carriers of germline mutations in one of 16 DNA damage repair genes (eg, *BRCA1*, *BRCA2*, and *CHEK2*) have been associated with an increased risk of developing aggressive prostate cancer.[4,5] Germline genetic testing to evaluate for inherited cancer susceptibility genes is now recommended in patients who are diagnosed with prostate cancer and have a relevant family history, or those who are diagnosed with advanced/high-risk disease.[7] Other genes implicated in hereditary prostate cancer are *MSH2* and *HOXB13*.[6] In addition to inherited genetics, common exposure to environmental and other risk factors may contribute to increased risk among patients with first-degree relatives with prostate cancer.[5]

Diet

The overall dietary factor associated with the lowest risk of developing prostate cancer appears to be adherence to a Mediterranean diet.[8] The typical Mediterranean diet is high in fruits, vegetables, legumes, fish, olive oil, and red wine, with low-to-moderate amounts of red meat, poultry, and dairy. In a meta-analysis that included approximately 1.5 million subjects, adherence to a Mediterranean diet was associated with a small, but significantly reduced risk of prostate cancer.[8]

Many individual dietary factors have been assessed to ascertain their role in the development or prevention of prostate cancer.[9] Green tea and lycopene are considered the most useful, and at least not harmful. Green tea consumption was associated with a reduced risk of prostate cancer in a small casecontrol study. Lycopene, obtained primarily from tomatoes, has been associated with a decreased risk of prostate cancer in small cohort studies, although a meta-analysis failed to show benefit for high tomato consumption.[9]

Consistent with the beneficial effects of the Mediterranean diet, red meat, and high milk intake have been clearly and consistently associated with an increased risk of prostate cancer in epidemiological studies.[9]

Other Factors

Benign prostatic hyperplasia (BPH) is a common problem among geriatric patients, affecting greater than 40% of men older than 70 years (see Chapter 104, "Benign Prostatic Hyperplasia"). BPH results in the urinary symptoms of increased hesitancy and frequency. Because prostate cancer affects a similar age group, and often has similar presenting signs and symptoms, the presence of BPH often complicates prostate cancer diagnoses. But importantly, a BPH diagnosis does not appear to increase the risk of developing prostate cancer.[3]

Interestingly, smoking has not been validated as a risk factor for developing prostate cancer. However, smokers with prostate cancer have almost a two-times greater risk of prostate cancer-related mortality when compared with nonsmokers with prostate cancer.[3] In addition, both clinical and translational study results did not detect an association between alcohol consumption and prostate cancer development.[10,11]

CHEMOPREVENTION

The use of 5-α-reductase inhibitors, finasteride and dutasteride, to prevent prostate cancer has been debated for more than a decade.[12–15] These drugs inhibit 5-α-reductase, an enzyme that converts testosterone to its more active form, dihydrotestosterone (DHT), which is involved in prostate epithelial proliferation. Both finasteride and dutasteride can falsely lower the PSA by about 50% in patients, and this must be considered when one interprets PSA in patients on these medications.[16] Although a number of large chemoprevention trials demonstrated a decreased risk of prostate cancer in patients who received 5-α-reductase inhibitors, this was coupled with an increased risk of developing more aggressive tumors. A survival benefit from chemoprevention with 5-α-reductase inhibitors has not been confirmed, although more contemporary analyses have called into question the association of 5-α-reductase inhibitors with the development of higher grade tumors.[17] Patients treated with 5-α-reductase inhibitors can experience adverse drug reactions, including gynecomastia, decreased libido, and erectile dysfunction.[13] Based on the concern for the development of more aggressive tumors, lack of survival benefit, and increased risk of adverse drug reactions, neither finasteride nor dutasteride is approved or recommended for preventing prostate cancer.[14,18]

Selenium and vitamin E, either alone or in combination, were evaluated as possible chemopreventive agents in the Selenium and Vitamin E Cancer Prevention Trial (SELECT), a clinical trial of healthy individuals. The results of this trial showed that selenium or vitamin E taken alone or together did not prevent prostate cancer. Furthermore, with a longer follow-up of that trial, dietary supplementation with vitamin E was found to significantly increase the risk of prostate cancer by 17%.[19] Other agents, including lycopene, green tea, nonsteroidal anti-inflammatory agents, isoflavones, and statins, have been evaluated for prostate cancer prevention, but none are recommended for routine use outside of a clinical trial.[20]

SCREENING

② Screening is not routinely recommended for all individuals at risk for prostate cancer. Rather, it is recommended that the individual discusses with their provider about risks versus benefits of screening. If prostate cancer screening is performed, the PSA test is the method of choice. PSA is a kallikrein-like serine protease, which liquefies seminal secretions and is produced by the prostate epithelial cells. Although PSA is specific for the prostate, it is not specific for cancer, and low specificity is a major limitation of the test. PSA may be elevated in patients with acute urinary retention, acute prostatitis, and prostatic ischemia or infarction, as well as BPH.[18,21] PSA elevations between 4.1 and 10 ng/mL (μg/L) cannot distinguish between BPH and prostate cancer, which limits the utility of the PSA test alone for the early detection of prostate cancer. Additionally, many patients with clinically significant prostate cancer do not have a serum PSA outside the reference range.[22]

Early detection of potentially curable prostate cancers is the goal of prostate cancer screening. For cancer screening to be beneficial, it must reliably detect cancer at an early stage, when intervention would decrease mortality. Whether prostate cancer screening fits these criteria is debatable.[23–26] The European Randomized Study of Screening for Prostate Cancer study demonstrated that compared to no PSA testing, PSA testing every 4 years decreased prostate cancer deaths in the screened group by about 1 per 1,000 men. However, the false-positive rate was 76% in the group that underwent PSA screening, which resulted in more than 13,000 unnecessary biopsies.[27] In the United States, the Prostate, Lung, Colon, and Ovarian Screening study showed no reduction in prostate cancer death between the annual screening group (PSA and DRE) and the usual care group, which is not surprising given the small reduction in death expected, and that about one-half of the patients in the usual care groups had PSA and/or DRE screening performed.[28] An updated systematic review found similar results in that PSA screening for prostate cancer may reduce the risk of prostate cancer mortality, but is associated with harms including false-positive results, biopsy complications, and over diagnosis in 20% to 50% of screen-detected prostate cancers. Early, active treatment for screen-detected prostate cancer may reduce the risk of metastatic disease, although the long-term impact of early, active treatment on prostate cancer mortality remains unclear. Active treatments for prostate cancer are frequently associated with sexual and urinary difficulties and thus can decrease quality of life for many patients.[29]

The US Preventive Services Task Force recommended that biologically male individuals aged 55 to 69 years make an individual decision about prostate cancer screening with their clinician (recommendation grade C) and recommended against routine screening for those aged 70 and older (recommendation grade D).[29] The American Urological Association does not recommend routine screening in biologic males between the ages of 40 and 54 years of average risk, but they recommend that the risks and benefits of prostate cancer screening are discussed with individuals aged 55 to 69 years.[23] For biologic males who elect to be screened, the frequency should be no more than 2 years, and screening every 5 years may be adequate. The American Society of Clinical Oncology recommends that asymptomatic biologically male individuals who have at least a 10-year life expectancy have an opportunity to make an informed decision about prostate cancer screening, including discussion of the uncertainties, risks, and potential benefits associated with screening.[26]

PATHOPHYSIOLOGY

The prostate gland is a solid, rounded, heart-shaped organ positioned between the neck of the bladder and the urogenital diaphragm (Fig. 154-1). The normal prostate is composed of acinar secretory cells arranged in a radial shape and surrounded by a foundation of supporting tissue. The size, shape, or presence of acini is almost always altered in the gland that has been invaded by prostatic carcinoma. Adenocarcinoma, the major pathologic cell type, accounts for more than 95% of prostate cancer cases.[30,31] Much rarer tumor types include small cell neuroendocrine cancers, sarcomas, and transitional cell carcinomas.

FIGURE 154-1

The prostate gland within the male genitourinary system.

Prostate cancer can be graded systematically according to the histologic appearance of the malignant cell and then grouped into well, moderately, or poorly differentiated grades.[31,32] Approximately 8 to 15 core biopsies are used to examine gland architecture and assess for malignancy. If malignancy is found then it is rated on a scale of 1 (well differentiated) to 5 (poorly differentiated). The two most common scores are added to give the Gleason pattern, with the most prevalent pattern represented as the first number (ie, 3+4 or 4+3). The biopsies are further classified into five Gleason groups, which are used to aid in prognosis, with Gleason Group 1 representing a Gleason score of ≤6 and Gleason Group 5 representing poorly differentiated disease with a Gleason score of 9 to 10. Poorly differentiated tumors grow rapidly (poor prognosis), while well-differentiated tumors grow slowly (better prognosis).

Metastatic spread can occur by local extension, lymphatic drainage, or hematogenous dissemination.[32,33] Lymph node metastases are more common in patients with large, undifferentiated tumors that invade the seminal vesicles. The pelvic and abdominal lymph node groups are the most common sites of lymph node involvement (see Fig. 154-1). Skeletal metastases from hematogenous spread are the most common sites of distant spread. Typically, the bone lesions are osteoblastic or a combination of osteoblastic and osteolytic. The most common site of bone involvement is the lumbar spine. Other sites of bone involvement include the proximal femur, pelvis, thoracic spine, ribs, sternum, skull, and humerus. The lung, liver, brain, and adrenal glands are the most common sites of visceral involvement, although these organs are not usually initially involved. About 25% to 35% of patients will have evidence of lymphangitic or nodular pulmonary infiltrates at autopsy. The prostate is rarely a site for metastatic involvement from other solid tumors.

Normal growth and differentiation of the prostate depend on the presence of androgens, specifically DHT.[33,34] The testes and the adrenal glands are the major sources of circulating androgens. Hormonal regulation of androgen synthesis is mediated through a series of biochemical interactions between the hypothalamus, pituitary, adrenal glands, and testes (Fig. 154-2). LHRH released from the hypothalamus stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary gland. LH complexes with receptors on the Leydig cell testicular membrane, and stimulates the production of testosterone and small amounts of estrogen. FSH acts on the Sertoli cells within the testes to promote the maturation of LH receptors and to produce an androgen-binding protein. Circulating testosterone and estradiol influence the synthesis of LHRH, LH, and FSH by a negative feedback loop operating at the hypothalamic and pituitary level.[35] Prolactin, growth hormone, and estradiol areimportant accessory regulators for prostatic tissue permeability, receptor binding, and testosterone synthesis.

FIGURE 154-2

Hormonal regulation of the prostate gland. ACTH, adrenocorticotropic hormone; DNA, deoxyribonucleic acid; GH, growth hormone; mRNA, messenger ribonucleic acid; PROL, prolactin.

Testosterone, the major androgenic hormone, accounts for 95% of the androgen concentration. The primary source of testosterone is the testes, but 3% to 5% of the testosterone concentration is derived from direct adrenal cortical secretion of testosterone or C19 steroids such as androstenedione.[32–34] 5α-reductase converts testosterone to DHT. When DHT is not bound to the AR, the AR remains inactive within the cytoplasm where it is bound to chaperone proteins (eg, heat shock protein 90 or HSP90).[36] However, when the AR is activated by DHT, the AR disassociates from heat shock protein 90, dimerizes, and then translocates into the nucleus where it binds to androgen response elements. AR binding to the androgen response elements regulates transcription of genes that regulate prostate cancer proliferation and cell survival (Fig. 154-2).[36,37]

In early-stage prostate cancers, aberrant tumor cell proliferation is promoted by the presence of androgens. For these tumors, the blockade of androgens induces tumor regression in most patients. Hormonal manipulations to ablate or reduce circulating androgens can occur through several mechanisms (Table 154-2).[33,34] The organs responsible for androgen production can be removed surgically (ie, orchiectomy, hypophysectomy, or adrenalectomy). Hormonal pathways that modulate prostatic growth can be interrupted at several steps (Fig. 154-2). Interference with LHRH or LH can reduce testosterone secretion by the testes.

TABLE 154-2

Hormonal Manipulations in Prostate Cancer

Androgen source ablation Adrenalectomy Orchiectomy Hypophysectomy	**Androgen synthesis inhibitors** Abiraterone acetate Ketoconazole

LHRH/GnRH antagonists Degarelix (antagonist) Relugolix (antagonist)	**Second-generation antiandrogens** Apalutamide Darolutamide Enzalutamide

Isolation of the naturally occurring hypothalamic decapeptide hormone, LHRH (also known as gonadotropin-releasing hormone or GnRH) has provided another group of effective agents for advanced prostate cancer treatment. The physiologic response to LHRH depends on both the dose and the mode of administration. Intermittent pulsed LHRH administration, which mimics the endogenous release pattern, causes sustained release of both LH and FSH, whereas high-dose or continuous intravenous administration of LHRH inhibits gonadotropin release due to receptor downregulation.[27] Structural modification of the naturally occurring LHRH and innovative delivery have produced a series of LHRH agonists that cause a similar downregulation of pituitary receptors and a decrease in testosterone production.[35]

Androgen synthesis can also be inhibited in the testes or in the adrenal gland. Antiandrogens inhibit the formation of the DHT-receptor complex and therefore interfere with androgen activity at the cellular level.[35] In advanced stages of disease, prostate cancer cells may survive and proliferate without the signals normally provided by circulating androgens.[35] When this occurs, the tumor is no longer sensitive to therapies that depend on androgen blockade. These tumors are often referred to as hormone refractory, androgen independent, or castration-resistant. Re-exposure to androgens can still cause these castration-resistant tumors to proliferate, but they have developed resistance mechanisms to androgen suppression alone. Thus, ADT must be continued in patients with castration-resistant disease (in addition to therapies with other mechanisms of action), despite evidence that the prostate cancer is no longer sensitive to ADT when used alone.

CLINICAL PRESENTATION

Before the implementation of routine screening, prostate cancers were frequently diagnosed after the onset of symptoms, including urinary hesitancy, retention, painful urination, hematuria, and erectile dysfunction. With the introduction of screening, most prostate cancers are now identified before the development of symptoms, although this may change as routine screening is no longer the norm.

CLINICAL PRESENTATION: Prostate Cancer

Localized Disease

- Usually asymptomatic

Locally Invasive Disease

- Ureteral dysfunction, frequency, hesitancy, and dribbling
- Impotence

Advanced Disease

- Back pain
- Spinal cord compression
- Lower extremity edema
- Pathologic fractures
- Anemia
- Weight loss

DIAGNOSIS AND STAGING

The information obtained from the diagnostic tests is used to stage the patient (Table 154-3). The eighth edition of the formal international classification system is the American Joint Committee on Cancer (AJCC) system (tumor, node, metastases [TNM]) (Table 154-4).

TABLE 154-3

Diagnostic and Staging Workup for Prostate Cancer

Initial tests	DRE
	PSA level
	Biopsy
Staging tests	Gleason score on biopsy specimen
	Bone imaging
	Pelvic/abdominal imaging (mpMRI)
	Complete blood count
	Liver function tests
	Serum phosphatases (acid/alkaline)
Additional staging tests (depends on tumor classification, PSA, and Gleason score)	• Obtain family cancer history/assess risk of germline genetic mutations • Estimate life expectancy • Somatic tumor mutation testing • Lymph node evaluation • Pelvic computed tomography • PMSA-targeted PET-CT imaging (eg, Ga 68 PSMA-11 and piflufolastat F 18)

CT, computed tomography; mpMRI, multi-parametric magnetic resonance imaging; PET, positron emission tomography; PMSA, prostate-specific membrane antigen.

TABLE 154-4

Staging and Classification System for Prostate Cancer

AJCC 8th edition Classification
$T_xN_xM_x$ (cannot be assessed)
$T_0N_0M_0$ (nonpalpable)
T: Tumor
T_0: No evidence of primary tumor
T_1: Clinically inapparent tumor not palpable
T_{1a}: Tumor incidental histologic finding in 5% or less of tissue resected
T_{1b}: Tumor incidental histologic finding in 5% or more of tissue resected
T_{1c}: Tumor identified by needle biopsy found in one or both sides, but not palpable

T_2: Tumor is palpable confined within the prostate
T_{2a}: Tumor involves one-half of one side or less
T_{2b}: Tumor involves more than one-half of one side, but not both sides
T_{2c}: Tumor involves both sides
T_3: Extraprostatic tumor that is not fixed or does not invade adjacent structures
T_{3a}: Extraprostatic extension (unilateral or bilateral)
T_{3b}: Tumor invades seminal vesicle(s)
T_4: Tumor is fixed or invades adjacent structures other than the seminal vesicles such as external sphincter, rectum, bladder, levator muscles, and/or pelvic wall
N: Regional Lymph Nodes
N_0: No positive regional lymph nodes
N_1: Metastasis in regional lymph nodes
M: Distant Metastasis
M_0: No distant metastasis
M_{1a}: Nonregional lymph node(s)
M_{1b}: Bone(s)
M_{1c}: Other site(s) with or without bone disease

③ The prognosis for patients with prostate cancer depends on the histologic grade (ie, Gleason score), the tumor size, and the local extent of the primary tumor.[31] The most important prognostic factor is the histologic grade because the degree of differentiation ultimately determines the stage of disease. Poorly differentiated tumors are highly associated with both regional lymph node involvement and distant metastases.[28]

Data from 2011 to 2017 showed that among all patients with prostate cancer, 5-year overall survival was estimated to be >99% when the disease is localized at diagnosis, and the 5-year survival rate for all stages combined is 98%. However, for individuals who are diagnosed initially with metastatic prostate cancer, 5-year survival drops to 30%. These same 2011 to 2017 data also showed that 5-year overall survival rates were estimated at 98% in White individuals and 96% in Black individuals.[1] For almost the same period, the survival rates for localized or regional disease and distant disease were also approximately the same in White and Black individuals in the United States.[1]

TREATMENT

Desired Outcomes

The desired outcome in early-stage prostate cancer is to minimize morbidity and mortality caused by prostate cancer.[7,38] The most appropriate therapy of early-stage prostate cancer is controversial. Early-stage disease may be treated with surgery, radiation, or expectant management. While surgery and radiation are curative, they are associated with significant morbidity and even mortality. Because the overall goal is to minimize morbidity and mortality associated with the disease, watchful waiting is appropriate in selected individuals. Advanced prostate cancer is not curable, and treatment should provide symptom relief and maintain quality of life. The mainstay of treatment for advanced prostate cancer is ADT, with a goal of reducing testosterone to castrate levels, with either surgical (eg, orchiectomy) or pharmacologic modalities (eg, LHRH agonist or LHRH/GnRH antagonist).

General Approach to Treatment

The initial treatment for prostate cancer depends primarily on the disease stage, the Gleason score, the presence of symptoms, and the life expectancy of the patient.[7] Prostate cancer is usually initially diagnosed by PSA and DRE, and then confirmed by a biopsy where the Gleason score is assigned. Asymptomatic patients with a low risk of recurrence may be managed by observation, radiation, or radical prostatectomy (Table 154-5). As patients with asymptomatic early-stage disease generally have an excellent 10-year survival, immediate morbidities of treatment must be balanced with the lower likelihood of dying from prostate cancer. More aggressive treatment of early-stage prostate cancer is generally reserved for younger individuals, although patient preference is a major consideration in all treatment decisions. In a patient with a normal life expectancy of less than 10 years, observation or radiation therapy may be offered. In those with a normal life expectancy of equal to or greater than 10 years, either active surveillance, radiation (external beam or brachytherapy), or radical prostatectomy with a pelvic lymph node dissection may be offered. Radiation therapy and radical prostatectomy are generally considered therapeutically equivalent for localized prostate cancer, although neither has been proven to be better than observation alone in those with low risks of recurrence.[39]

TABLE 154-5

Initial Management of Prostate Cancer Based on Expected Survival and Recurrence Risk

Recurrence Risk	Expected Survival (Years)	Initial Therapy
Very Low		
Has all of the following: ○ T_{1c} ○ Gleason group 1 ○ PSA less than 10 ng/mL (mcg/L) ○ Fewer than 3 prostate biopsies positive, ≤50% cancer in each core ○ PSA density <0.15 ng/mL/g (mcg/L/g)	<10	Observation
	10-20	Active surveillance
	20 or more	Active surveillance or radical prostatectomy or radiation therapy
Low		
Has all of the following but does not qualify for very low risk: ○ T_1-T_{2a} ○ Gleason Group 1 ○ PSA less than 10 ng/mL (mcg/L)	10 or more	Active surveillance or radical prostatectomy or radiation therapy
	<10	Observation
Intermediate		
• Has no high-risk group features • Intermediate risk factors (IRFs): ○ T_{2b}-T_{2c} ○ Gleason Group 2-3 ○ PSA10-20 ng/mL (mcg/L)		

Favorable Intermediate risk Has all of following: ◦ Only 1 intermediate risk factor ◦ Gleason Grade Group 1-2 ◦ <50% biopsy cores positive	10 or more	Active surveillance or radical prostatectomy +/− pelvic lymph node dissection or radiation therapy
	<10	Observation or Radiation therapy or Brachytherapy
Unfavorable intermediate risk Has one or more of the following: ◦ 2 or 3 intermediate risk factors ◦ Gleason Grade Group 3 ◦ ≥50% biopsy cores positive	10 or more	Radical prostatectomy +/− pelvic lymph node dissection or radiation therapy + ADT[a,b] or radiation therapy + brachytherapy +/− ADT
	<10	Observation or radiation therapy + ADT[a,b] or radiation therapy + brachytherapy +/− ADT
High		
Has no very-high risk features and has exactly ONE high-risk feature: ◦ T_{3a} or ◦ Gleason Grade Group 4-5 or 8 ◦ PSA >20 ng/mL (mcg/L)	5 or more	Radiation therapy + ADT +/− docetaxel or radiation therapy + ADT +brachytherapy or radical prostatectomy and pelvic lymph node dissection
Very High		
Has at least one of the following: ◦ T_{3b}-T_4 ◦ Primary Gleason pattern 5 ◦ 2 or 3 high-risk features ◦ 4 cores with Gleason Grade Group 4 or 5	5 or more	Radiation therapy + ADT +/− docetaxel or radiation therapy + ADT +brachytherapy or radical prostatectomy and pelvic lymph node dissection
Locally Advanced/Metastatic disease		
Any T, N_1	5 or more	ADT +/-abiraterone and prednisone or radiation therapy + ADT +/− with or without abiraterone and prednisone)
Any T, Any N, M_1		ADT alone or in addition to: Apalutamide

		Abiraterone with prednisone Docetaxel Enzalutamide

[a] ADT therapy to achieve serum testosterone levels <50 ng/dL (1.7 nmol/L).

[b] LHRH agonists, LHRH/GnRH antagonists, or surgical castration are equivalent.

A systematic review of 18 randomized trials and 473 observational studies compared the effectiveness and potential complications across prostate cancer treatment modalities. However, the analysis revealed that a paucity of high-quality available evidence limited comparisons of effectiveness between radiation, radical prostatectomy, and ADT. While the adverse drug reaction profiles were similar, the severity varied among the treatments.[40] Because radiation and prostatectomy have significant and immediate mortality when compared with expectant management alone, many patients may elect to postpone therapy until symptoms develop.

Individuals with T_{2b} and T_{2c} disease, a Gleason Group 2-3, or a PSA ranging from 10 to 20 ng/mL (µg/L) are considered at intermediate risk for prostate cancer recurrence. The intermediate-risk category is further divided into favorable and unfavorable intermediate risk, with more aggressive treatment recommended for those with more intermediate risk factors present at diagnosis.[7] Individuals with less than a 10-year expected survival may be offered observation or radiation therapy. Individuals with favorable risk may also be offered brachytherapy alone. In some cases, individuals with unfavorable risk and less than a 10-year expected survival may be also offered either radiation therapy with or without 4 to 6 months of neoadjuvant ADT, or radiation therapy plus brachytherapy with or without 4 to 6 months of neoadjuvant ADT. Individuals with favorable risk and a greater than or equal to 10-year life expectancy may be offered active surveillance, radical prostatectomy, with or without a pelvic lymph node dissection, or radiation therapy. Individuals with unfavorable risk and a greater than or equal to 10-year life expectancy may be offered radical prostatectomy, with or without a pelvic lymph node dissection, radiation therapy with or without 4 to 6 months of neoadjuvant ADT, or radiation therapy plus brachytherapy with or without 4 to 6 months of neoadjuvant ADT (Table 154-5).[7]

The treatment of patients at high or very-high risk of recurrence (stage T_3, a Gleason score ranging from 8 to 9, or a PSA value greater than 20 ng/mL [µg/L]) may be treated with ADT for 1.5 to 3 years combined with radiation therapy with or without brachytherapy (Table 154-5). Selected individuals with a low tumor volume may receive a radical prostatectomy with a pelvic lymph node dissection and additional therapy based on pathological evaluation. Docetaxel, in addition to radiation and ADT, can also be considered for patients in this risk recurrence group.[7]

④ Patients with T_{3b} and T_4 disease have a very-high risk of recurrence and are usually not candidates for radical prostatectomy because of extensive local spread of disease.[7] ADT with a LHRH agonist plus an antiandrogen should be used either prior to, concurrent with, or following radiation therapy for patients with locally advanced prostate cancer to improve outcomes over radiation therapy alone in patients with localized prostate cancer. Androgen ablation should be instituted at diagnosis rather than waiting for symptomatic disease or progression to occur. In a randomized clinical trial of 500 patients with locally advanced prostate cancer who were randomized to either immediate initiation of ADT (either surgical or pharmacologic) or deferred hormonal therapy, patients who received immediate therapy had a median actuarial cause-specific survival of 7.5 years for immediate treatment as compared with 5.8 years for deferred treatment.[41]

⑤ Systemic therapy for nonmetastatic, castration-naïve disease, where the disease has not yet become resistant to ADT therapy, may include either orchiectomy, LHRH agonist with or without a first-generation antiandrogen (ie, combined androgen blockade [CAB]), GnRH antagonist, or observation. In patients with lymph node involvement (N_1) disease, abiraterone with a corticosteroid (eg, prednisone) can be used in addition to ADT (Table 154-6).[7]

Table 154-6

First-Line Systemic Treatment Options for Advanced and Metastatic Prostate Cancer in Treatment-Naïve Patients

	Locally Advanced/Non-metastatic	**Metastatic**
Castration-naïve (ADT initiated to achieve testosterone <50 ng/mL [mcg/L] in all cases)	● ADT ● ADT + abiraterone + corticosteroid[a]	● ADT ● ADT + abiraterone + corticosteroid[a] ● ADT + apalutamide ● ADT + docetaxel ● ADT + enzalutamide
Castration-resistant (ADT continued to maintain testosterone <50 ng/mL [mcg/L] in all cases)	● Apalutamide ● Darolutamide ● Enzalutamide	● Abiraterone + corticosteroid[b] ● Enzalutamide ● Docetaxel + prednisone ● Radium-223 (if symptomatic bone metastases) ● Sipuleucel-T

[a] Treatment-naïve refers to those who have not received novel hormone therapy or docetaxel.

[b] Choice of corticosteroid is dependent on multiple factors, including abiraterone formulation.

Data from Reference 7.

6 ADT in addition to one of the following: docetaxel (six cycles), abiraterone with a corticosteroid (eg, prednisone), enzalutamide, or apalutamide are recommended options for patients with metastatic castration-naïve disease (Table 154-6).[7]

When patients progress despite adequate androgen suppression, their disease is considered castration-resistant. Importantly, patients may progress on initial therapy without evidence of disease on scans. An increase in PSA or a rapid PSA doubling time (generally less than 10 months), could be indicative of progression and a biochemical recurrence. The development of new symptoms should also prompt a work-up for disease progression. Importantly, further therapy is determined by the presence of symptomatic disease, or whether the metastatic progression is manifested as only a rising PSA (Table 154-6).[7]

7 For patients with nonmetastatic (M_0) castration-resistant disease, observation plus continued ADT is preferred if PSA doubling time is greater than 10 months. However, for patients with nonmetastatic castration-resistant prostate cancer who have a PSA doubling time less than or equal to 10 months, systemic therapy is recommended. Preferred systemic therapies for these patients include continuing ADT to maintain serum levels of testosterone less than 50 ng/dL (1.7 nmol/L) and a second-generation antiandrogen (eg, apalutamide, darolutamide, or enzalutamide) (Table 154-6).[7]

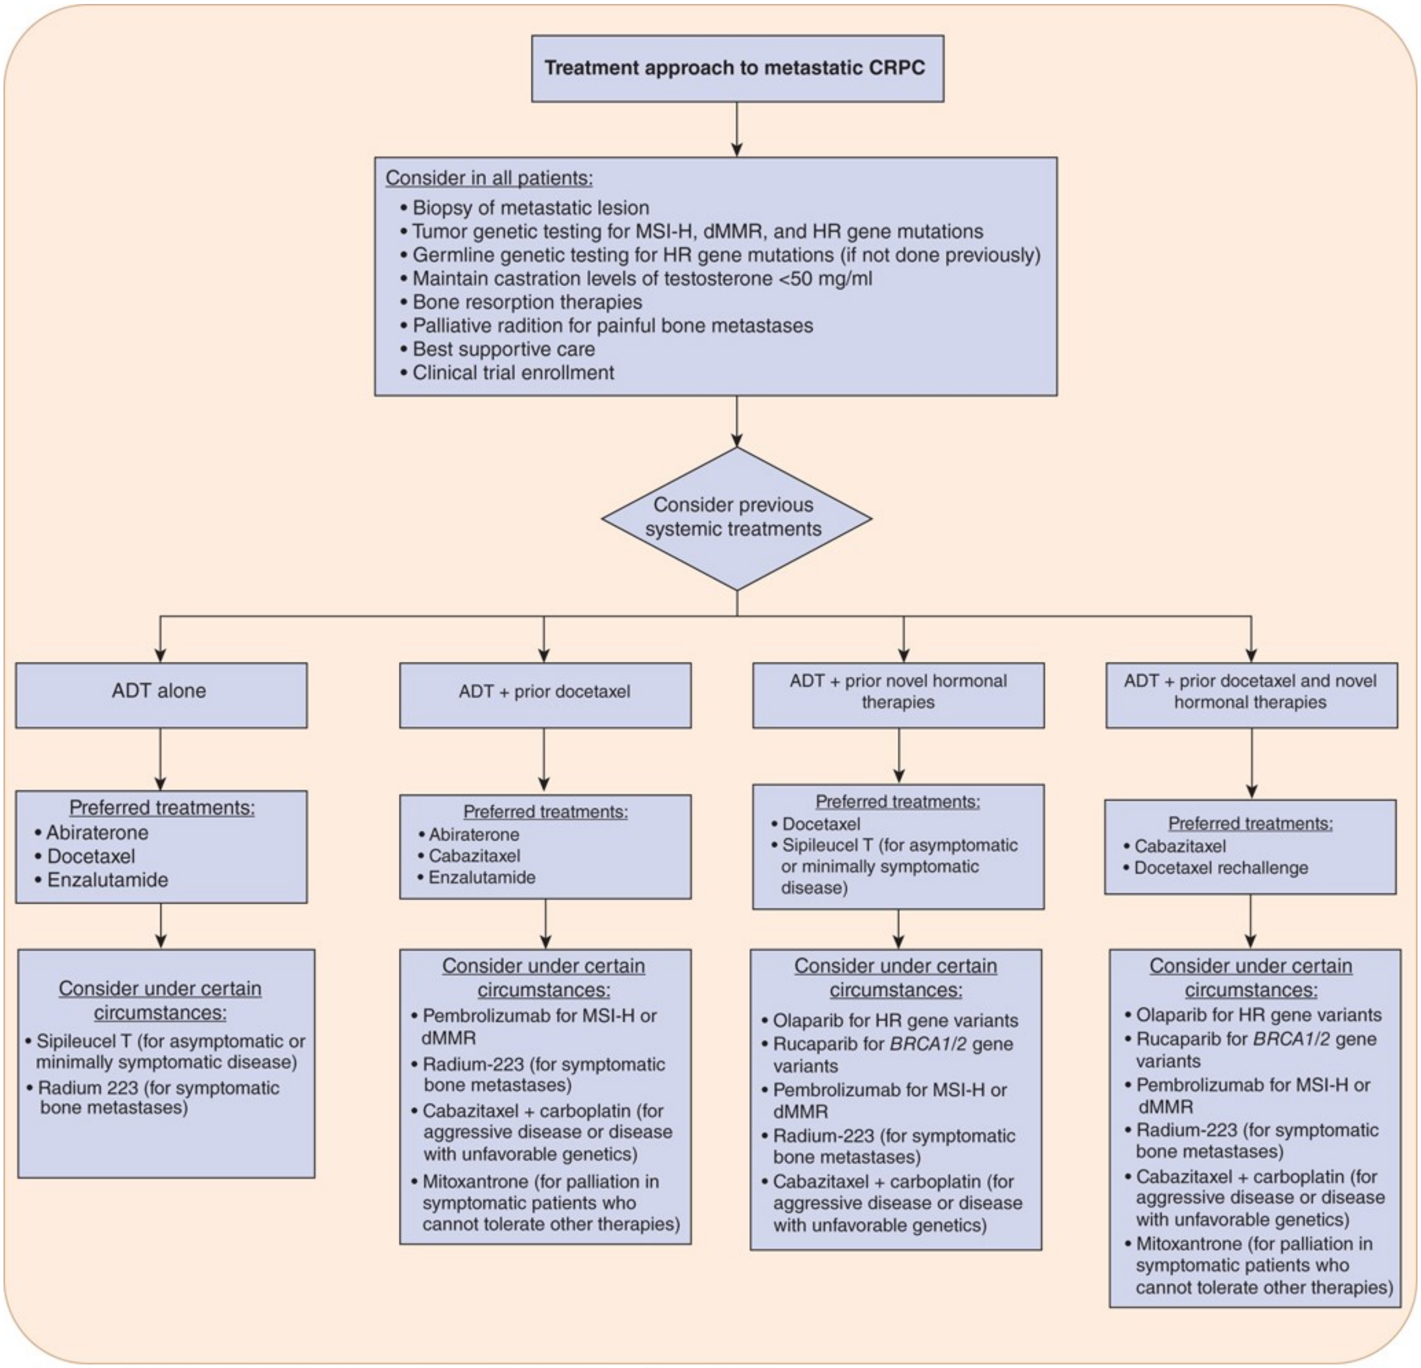
Patients with metastatic (M_1) castration-resistant prostate cancer should receive best supportive care in addition to other treatments (Fig. 154-3). ADT should continue, and initiating denosumab or an intravenous bisphosphonate should be considered in patients with bone metastases (see the discussion of LHRH agonists in the "Pharmacotherapy" section for more information). Palliative radiation therapy to bony metastases is also an option that may be utilized in these patients to provide relief of symptoms. When it comes to treatment selection for patients with metastatic castration-resistant prostate cancer, consideration should be given to previous lines of treatment, and providers should strive to choose an agent with a mechanism of action different from any therapies that the patient has failed (Fig. 154-3). Preferred first-line treatments (in conjunction with continuing ADT) include docetaxel plus prednisone, enzalutamide, or abiraterone. Sipuleucel-T, an immunotherapeutic, is also an option for patients without visceral metastases and who are clinically asymptomatic. Radium-223, an alpha emitter, is recommended for patients with bony metastases (and without evidence of visceral disease) (Table 154-6).[7]

8 In castration-resistant prostate cancer, genetic testing on tumor tissue (along with germline genetic testing if not already completed) is recommended for MSI-H or dMMR and HR gene mutations (eg, *BRCA1/2*) is recommended. Those whose tumors test positive for MSI-H, dMMR, or TMB greater than or equal to 10 mut/Mb are eligible for treatment with the programmed cell death receptor 1, or PD1, inhibitor pembrolizumab. Evidence of pathogenic gene mutations in genes involved in HR indicates eligibility for olaparib, while the presence of pathogenic *BRCA1/2* mutations specifically indicate eligibility for rucaparib. Other agents include cabazitaxel,

which can be used if the patient has failed docetaxel, or mitoxantrone, which can be considered when patients present with visceral metastases and cannot tolerate other therapies (Fig. 154-3).[7]

FIGURE 154-3

Treatment of metastatic castration-resistant prostate cancer. (*Data from Reference 7.*)



Treatment approach to metastatic CRPC
Consider in all patients:
• Biopsy of metastatic lesion
• Tumor genetic testing for MSI-H, dMMR, and HR gene mutations
• Germline genetic testing for HR gene mutations (if not done previously)
• Maintain castration levels of testosterone <50 mg/ml
• Bone resorption therapies
• Palliative radition for painful bone metastases
• Best supportive care
• Clinical trial enrollment
Consider previous systemic treatments
ADT alone
ADT + prior docetaxel
ADT + prior novel hormonal therapies
ADT + prior docetaxel and novel hormonal therapies
Preferred treatments:
• Abiraterone
• Docetaxel
• Enzalutamide
Preferred treatments:
• Abiraterone
• Cabazitaxel
• Enzalutamide
Preferred treatments:
• Docetaxel
• Sipileucel T (for asymptomatic or minimally symptomatic disease)
Preferred treatments:
• Cabazitaxel
• Docetaxel rechallenge
Consider under certain circumstances:
• Sipileucel T (for asymptomatic or minimally symptomatic disease)
• Radium 223 (for symptomatic bone metastases)
Consider under certain circumstances:
• Pembrolizumab for MSI-H or dMMR
• Radium-223 (for symptomatic bone metastases)
• Cabazitaxel + carboplatin (for aggressive disease or disease with unfavorable genetics)
• Mitoxantrone (for palliation in symptomatic patients who cannot tolerate other therapies)
Consider under certain circumstances:
• Olaparib for HR gene variants
• Rucaparib for *BRCA1/2* gene variants
• Pembrolizumab for MSI-H or dMMR
• Radium-223 (for symptomatic bone metastases)
• Cabazitaxel + carboplatin (for aggressive disease or disease with unfavorable genetics)
Consider under certain circumstances:
• Olaparib for HR gene variants
• Rucaparib for *BRCA1/2* gene variants
• Pembrolizumab for MSI-H or dMMR
• Radium-223 (for symptomatic bone metastases)
• Cabazitaxel + carboplatin (for aggressive disease or disease with unfavorable genetics)
• Mitoxantrone (for palliation in symptomatic patients who cannot tolerate other therapies)

Nonpharmacologic Therapy

Observation/Active Surveillance

Observation is a treatment approach utilized in men with a shorter life expectancy and lower risk of disease. Observation involves monitoring the course of disease with laboratory testing and imaging, and starting palliative treatment if the cancer progresses. The advantages of observation are avoiding the adverse drug reactions associated with definitive therapies, such as radiation and radical prostatectomy, and minimizing the risk of unnecessary therapies. The major disadvantage of observation is the risk that cancer progresses and requires more intensive therapy. Active surveillance is similar to observation, although it may involve more invasive surveillance prostate biopsies. Those receiving active surveillance would generally be eligible for more aggressive treatment approaches upon progression.[7]

Orchiectomy

Bilateral orchiectomy, or surgical removal of the testes, is a form of ADT that rapidly reduces circulating androgens to castrate levels (less than 50 ng/dL [1.7 nmol/L]).[25] However, many patients are not surgical candidates because of advanced age, and other patients find this procedure psychologically unacceptable.[30] Orchiectomy is the preferred initial treatment in patients with impending spinal cord compression or ureteral obstruction, given theirrapid onset.

Radiation

The two commonly used methods for radiation therapy are external beam radiotherapy and brachytherapy.[7] In external beam radiotherapy, doses of 70 to 75 Gy (7,000-7,500 rad) are delivered in 35 to 41 fractions in patients with low-grade prostate cancer and 75 to 80 Gy (7,500-8,000 rad) for those with intermediate- or high-grade prostate cancer. Brachytherapy involves the permanent implantation of radioactive beads of 145 Gy (14,500 rad) ^{125}iodine or 124 Gy (12,400 rad) ^{103}palladium and is generally reserved for individuals with low-risk cancers. Radiation therapy may also be given after surgery in patients with localized disease. Acute complications from radiation therapy include cystitis, proctitis, hematuria, urinary retention, penoscrotal edema, and impotence (30% incidence).[21,31] Chronic complications include proctitis, diarrhea, cystitis, enteritis, impotence, urethral stricture, and incontinence.[30,31] Because radiation therapy and radical prostatectomy have significant and immediate adverse effects compared with observation alone, many patients elect to postpone therapy until prostate cancer symptoms develop.

Radical Prostatectomy

Radical prostatectomy involves surgical removal of the prostate. Complications from radical prostatectomy include blood loss, stricture formation, incontinence, lymphocele, fistula formation, anesthetic risk, and impotence. Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year. However, even in patients with good preoperative sexual health, many do not return to baseline after surgery even with the assistance of erectile dysfunction treatments.[42] Nerve-sparing radical prostatectomy can be performed in many patients; 50% to 80% regain sexual potency within the first year. The surgery can be accompanied by a pelvic lymph node dissection to determine if the disease has spread to any regional nodes.

Pharmacotherapy

LHRH Agonists

LHRH agonists are a reversible method of androgen ablation and are as effective as orchiectomy in treating prostate cancer.[7,43] Currently available LHRH agonists include leuprolide, leuprolide depot, leuprolide implant, triptorelin depot, triptorelin implant, and goserelin acetate implant (Table 154-7). The leuprolide depot formulation contains leuprolide acetate in coated pellets. The dose is administered intramuscularly, and the coating dissolves at different rates to allow sustained leuprolide levels throughout the dosing interval. Goserelin acetate implant contains goserelin acetate dispersed in a plastic matrix of D,L-lactic, and glycolic acid copolymer and is administered subcutaneously. Hydrolysis of the copolymer material provides continuous release of goserelin over the dosing period.

TABLE 154-7

Hormonal Therapies for Prostate Cancer

Drug	Usual Dose	Adverse Drug Reactions	Hepatic/Renal Adjustments	Monitoring Parameters	Drug Interactions	Administration
First-Generation Antiandrogens						
Bicalutamide	50 mg/day PO (up to 150 mg/day—unlabeled use)	Gynecomastia Hot flashes Gastrointestinal	Discontinue if ALT >2 times upper limit of	Serum transaminases should be monitored prior to start of	Inhibits CYP3A4 May increase	May be taken with or without food

		disturbances (diarrhea) Decrease libido LFT abnormalities Breast tenderness	normal or patient develops jaundice	therapy and monthly for the first 4 months, then periodically thereafter Periodic monitoring of CBC, EKG, echocardiograms, serum testosterone, luteinizing hormone, and PSA	the concentration of vitamin K antagonists	
Flutamide	750 mg/day PO	Gynecomastia Hot flashes Gastrointestinal disturbances (diarrhea) Loss of libido LFT abnormalities Breast tenderness Methemoglobinemia	Contraindicated in patients with hepatic impairment No dosage adjustment necessary in chronic renal impairment	Serum transaminases should be monitored prior to start of therapy and monthly for the first 4 months, then periodically thereafter Monitor for tumor reduction, PSA, testosterone/estrogen, and phosphatase serum levels	Substrate of CYP1A2 and CYP3A4	Administered orally in three divided doses; capsule may be opened into applesauce, pudding, or other soft foods
Nilutamide	300 mg/day PO for first month then 150 mg/day	Gynecomastia Hot flashes Gastrointestinal Disturbances (constipation) LFT abnormalities Breast tenderness Visual disturbances (impaired dark adaptation) Alcohol intolerance Interstitial pneumonitis	Contraindicated in patients with hepatic impairment Discontinue if ALT >2 times upper limit of normal or patient develops jaundice	Serum transaminases should be monitored prior to start of therapy and monthly for the first 4 months, then periodically thereafter Chest x-ray at baseline and consideration of pulmonary function testing (at baseline), PSA periodically	Substrate of CYP2C19 and weak inhibitor of CYP2C19	May be taken with or without food
Second-Generation Antiandrogens						
Apalutamide	240 mg/day PO	Gastrointestinal disturbances (diarrhea, nausea) Hot flashes Fatigue Hyperthyroidism Hypertension Rash Decreased weight Falls and fractures Peripheral edema Seizures	No adjustment necessary for renal or hepatic impairment	Complete blood counts baseline and periodically LFTs baseline and periodically TSH at baseline and every 4 months, PSA periodically	Strong inducer of CYP3A4 and CYP2C19, and a weak inducer of CYP2C9	May be taken with or without food

Darolutamide	1,200 mg/day PO	Fatigue Gastrointestinal disturbances (diarrhea, constipation, nausea) Rash Musculoskeletal disorders (back pain, arthralgias, pain in an extremity) Falls, including accidents/bone fractures Hypertension Seizures	For moderate hepatic impairment or severe renal impairment (not on dialysis): dose should be reduced to 600 mg/day	Complete blood counts baseline and periodically LFTs baseline and periodically, PSA periodically	BCRP transporter Inhibitor Darolutamide inhibits OATP1B1 and OATP1B3	Take with food
Enzalutamide	160 mg/day PO	Gastrointestinal disturbances (diarrhea) Musculoskeletal disorders (back pain, arthralgias, muscle pain, weakness) Asthenia Peripheral edema CNS (headache, dizziness) Seizures LFT abnormalities	No adjustment necessary for renal or hepatic impairment	Complete blood counts baseline and periodically LFTs baseline and periodically, PSA periodically	Strong CYP3A4 and moderate CYP2C9 and CYP2C19 inducer; avoid CYP3A4, CYP2C9, and CYP2C19 sensitive substrates. CYP2C8 substrate, avoid strong inducers and inhibitors of CYP2C8. If vitamin K antagonists are necessary, conduct additional INR monitoring	May be taken with or without food
Androgen Synthesis Inhibitor						
Abiraterone acetate	Abiraterone acetate: 1,000 mg/day PO + prednisone 5 mg daily PO (castration-naïve) or BID PO (CRPC) Micronized abiraterone: 500 mg	Gastrointestinal disturbances (diarrhea) Edema Hypokalemia Hypophosphatemia LFT abnormalities	250 mg daily for Child Pugh Class B; avoid use in Child Pugh Class C Withhold treatment if	Serum transaminases should be monitored prior to start of therapy, every 2 weeks for 3 months, then monthly thereafter Monitor for signs and	Substrate of CYP3A4. Use with caution with CYP3A4 inhibitors and inducers.	For standard abiraterone, administer on an empty stomach, at least 1 hour before and 2

	daily PO + methylprednisolone 4 mg BID PO (CRPC)	Hypertriglyceridemia	LFTs >5 times the ULN or bilirubin >3 ULN	symptoms of adrenocorticoid insufficiency; monthly for hypertension, hypokalemia, and fluid retention, PSA periodically	Inhibits CYP1A2, CYP2C19, CYP2C8, CYP2C9, CYP2D6, CYP3A4, and P-glycoprotein Use sensitive substrates with caution	hours after food (micronized abiraterone can be given regardless of food)
Luteinizing-Hormone Releasing Hormone Agonists						
Goserelin	3.6 mg SQ implant every month 10.8 mg SQ implant every 3 months	Hot flashes Decreased libido Gynecomastia Osteoporosis Fatigue Weight gain	No adjustment necessary for renal or hepatic impairment	Monitor bone mineral density, serum calcium, and cholesterol/lipids, PSA periodically	May diminish the effects of antidiabetic agents	Vary injection site
Leuprolide	7.5 mg IM every month 22.5 mg IM every 3 months 30 mg IM every 4 months 45 mg IM every 6 months	Hot flashes Decreased libido Gynecomastia Osteoporosis Fatigue Weight gain	No adjustment necessary for renal or hepatic impairment	Serum testosterone ~4 weeks after initiation, PSA, blood glucose, and $HgbA_{1c}$ prior to initiation and periodically thereafter, PSA periodically	May diminish the effects of antidiabetic agents	Vary injection site
Triptorelin	3.75 mg IM every month 11.25 mg IM every 3 months 22.5 mg IM every 6 months	Hot flashes Decreased libido Gynecomastia Osteoporosis Fatigue Weight gain	No adjustment necessary for renal or hepatic impairment	Monitor serum testosterone levels and PSA periodically	May diminish the effects of antidiabetic agents	Vary injection site
Luteinizing-Hormone Releasing Hormone/Gonadotropin-Releasing Hormone Receptor Antagonists						
Degarelix	240 mg SQ loading dose 80 mg SQ every 28 days (following 28 days after loading dose)	Hot flashes Decreased libido Gynecomastia Osteoporosis Fatigue Weight gain	Use with caution with CL_{cr} <50 mL/min (0.83 mL/s) Do not use in patients with severe hepatic impairment	PSA periodically, serum testosterone monthly until castration achieved then every other month, LFTs at baseline in addition to serum electrolytes and bone mineral density	Use with caution with agents that may increase QTc interval	Vary injection site
Relugolix	360 mg PO followed	Hot flashes,	No adjustment	PSA periodically, LFTs	Use with	May be taken

	by 120 mg PO daily	hypergylcemia, hypertriglyceridemia, musculoskeletal pain, fatigue	necessary for renal or hepatic impairment	and serum electrolytes at baseline and periodically; bone mineral density periodically	caution with agents that may increase QTc interval; Use with caution with CYP3A4 inhibitors and P-glycoprotein inhibitors	with or without food

ALT, alanine aminotransferase; BID, twice daily; BRCP, breast cancer resistance protein; CBC, complete blood count; CL$_{cr}$, creatinine clearance; CNS, central nervous system; CRPC, castrate-resistant prostate cancer; CYP, cytochrome P450; EKG, electrocardiogram; HgbA$_{1c}$, hemoglobin A1$_{c}$; IM, intramuscular injection; INR, international normalized ratio; LFT, liver function test; PO, oral administration; PSA, prostate surface antigen; QTc, corrected QT interval; SQ, subcutaneous injection; TSH, thyroid stimulating hormone; ULN, upper limit of normal.

Data from References 55–65, 71.

Several randomized trials have demonstrated that leuprolide, goserelin, and triptorelin are effective agents when used alone in patients with advanced prostate cancer. Response rates of around 80% have been reported.[34] The currently available LHRH agonists or the dosage formulations have not been directly compared in clinical trials, but a meta-analysis showed no significant differences in efficacy or toxicity between leuprolide, goserelin, and orchiectomy.[44] Triptorelin is a more recent approval that is generally considered equally effective. Therefore, the choice between the three agents is usually made based on cost and patient and physician preference for a dosing schedule.

The most common adverse drug reactions reported with LHRH agonist therapy include a disease flare during the first week of therapy for patients with metastatic disease, hot flashes, erectile impotence, decreased libido, and injection-site reactions.[34] The disease flare is caused by an initial induction of LH and FSH by the LHRH agonist leading to an initial phase of increased testosterone production, and manifests clinically as either increased bone pain or increased urinary symptoms.[35] This flare reaction usually resolves after 2 weeks and has a similar onset and duration pattern for the depot LHRH products.[44,45] Tumor flare can be minimized by initiating an antiandrogen before the administration of the LHRH agonist and continuing for 2 to 4 weeks.[35] LHRH agonist monotherapy can be used as initial therapy, with response rates similar to those for orchiectomy. Caution should be exercised if initiating LHRH agonist therapy in patients with widely metastatic disease involving the spinal cord or having the potential for ureteral obstruction because irreversible complications may occur.

Another potentially serious complication of ADT is a decrease in bone mineral density leading to an increased risk for osteoporosis, osteopenia, and skeletal fractures. During initial therapy, bone mineral density of the hip and spine decreases by 2% to 3%.[46] Additionally, ADT has been associated with a 21% to 45% relative increase in fracture risk.[47–49] Therefore, most clinicians recommend that patients with increased risk for fracture based on the Fracture Assessment Tool, or FRAX, who are starting long-term ADT should have a baseline bone mineral density assessment performed, and all patients should have a bone mineral density assessment performed 1 year after initiating ADT. These individuals should also be initiated on a calcium and vitamin D supplement, based on the same guidance for the general population from the National Osteoporosis Foundation guidelines (see Chapter 112, "Osteoporosis," for more information).[7,35]

In addition, an antiresorptive agent, either zoledronic acid, alendronate, or denosumab should be initiated in men with osteoporosis at the same schedule and doses used in the treatment of the general population with osteoporosis (see Chapter 112, "Osteoporosis," for more information).[7] In men with metastatic castration-resistant prostate cancer and bone metastases, zoledronic acid or denosumab should be considered to reduce skeletal-related events (SREs). A meta-analysis combined data from three identically designed double-blind randomized controlled trials that compared the efficacy and safety of denosumab at a dose of 120 mg every 4 weeks with that of zoledronic acid at a dose of 4 mg administered IV every 4 weeks.[50] Almost 6,000 patients with breast and prostate cancer and multiple myeloma were included in the meta-analysis. Denosumab is superior to zoledronic acid in reducing the risk of first skeletal-related event (SRE) by 17% and prolonging the median time-to-first SRE was 8 months. The benefits were consistent across tumor types evaluated, and the incidence of adverse drug reactions was not significantly different between the denosumab and zoledronic acid groups.[50]

ADT has also been associated with a higher incidence of metabolic effects. In a landmark population-based trial, patients treated with an ADT using an LHRH agonist had a greater risk of new-onset diabetes, coronary artery disease, and myocardial infarctions.[51] However, it is not clear whether ADT increases the risk of cardiovascular death. A published meta-analysis of eight trials with 4,141 patients treated with ADT evaluated prostate cancer-specific mortality and all-cause mortality.[52] The trials included patients with nonmetastatic disease who were treated with immediate predominantly LHRH agonist–based ADT versus no immediate ADT (control group). The risk of cardiovascular death for ADT versus control was not significantly different, and these results suggest that ADT does not increase cardiovascular mortality. Patients receiving ADT should be screened for cardiovascular disease and diabetes and appropriate interventions to prevent and treat these complications should be initiated.[7]

LHRH/GnRH Antagonists

An alternative to LHRH agonists are the approved GnRH antagonists, degarelix, and relugolix. Degarelix and relugolix work by binding reversibly to GnRH receptors in the pituitary gland, which reduces the production of testosterone to castrate levels. The major advantage of the GnRH antagonists over LHRH agonists is the rapidity at which they reduce testosterone levels. Castration levels are achieved in 7 days or less with both degarelix and relugolix, as compared with 28 days with leuprolide. Tumor flare does not occur with either GnRH antagonist, and antiandrogens are not required.

Degarelix is equivalent to leuprolide in lowering testosterone levels for up to 1 year. Degarelix is available as 40 and 20 mg/mL vials for subcutaneous injection, and the starting dose is 240 mg followed by 80 mg every 28 days. The starting dose should be divided into two 120-mg injections.[53] Degarelix has not been studied in combination with antiandrogens, and routine use of the combination is not recommended. The most frequently reported adverse reactions are mild to moderate in nature and include transient injection site reactions, including pain, and erythema, and hot flashes. Other adverse drug reactions include elevations in liver function tests, which occur in about 10% of patients. These individuals should also be initiated on a calcium and vitamin D supplement, based on the same guidance for the general population from the National Osteoporosis Foundation guidelines (see Chapter 112, "Osteoporosis," for more information).[7,35,53]

Relugolix is an oral LHRH antagonist. In a phase 3 trial, patients administered relugolix (120 mg once daily after a single 360 mg oral loading dose) was evaluated against leuprolide. Relugolix demonstrated similar testosterone suppression to leuprolide, but in contrast to leuprolide, testosterone suppression was quickly reversible for those receiving relugolix, underscoring the need for adherence. But most importantly, in contrast to the other FDA-approved LHRH agonists and GnRH antagonists, there does not seem to be an increased cardiovascular risk with relugolix. In patients with pre-existing cardiovascular disease the incidence of major cardiovascular events was lower in patients treated with relugolix than patients treated with leuprolide (3.6% vs 17.8%).[54] Hot flashes, hypergylcemia, hypertrigylceridemia, musculoskeletal pain, fatigue were common toxicities, and providers should use with caution with medications that increase QTC interval, or are inhibitors of cytochrome P450 (CYP) 3A4 or the p-glycoprotein(P-gp) efflux transporter (Table 154-7).[55–59]

Antiandrogens

The first-generation antiandrogens include flutamide, bicalutamide, and nilutamide. Three second-generation antiandrogens, apalutamide, enzalutamide, and darolutamide, are currently available (Table 154-7).[55–65] Antiandrogens have been used as monotherapy in previously untreated patients, but a meta-analysis showed that monotherapy with antiandrogens is less effective than LHRH agonists.[44] Therefore, for advanced prostate cancer, flutamide, bicalutamide, and nilutamide are indicated only in combination with ADT. Flutamide and bicalutamide are indicated in combination with an LHRH agonist, and nilutamide is indicated in combination with orchiectomy.[66] Antiandrogens can reduce the symptoms from the flare phenomenon associated with LHRH agonist therapy in patients with metastatic disease.[7,35,66]

As with first-generation antiandrogens, second-generation antiandrogens do not lower androgen levels, but inhibit androgen receptor signaling by competitively inhibiting androgen binding without stimulation of the androgen receptor. Second-generation antiandrogens may have an advantage over the currently available first-generation antiandrogen agents because they inhibit AR nuclear translocation and AR binding to DNA and coactivator recruitment, which leads to a reduction of AR-mediated transcription of genes known to promote prostate cancer proliferation (Fig. 154-2). Enzalutamide also has a greater affinity for the AR, and has shown activity in patients resistant to first-generation antiandrogens. Initially approved only after docetaxel failure, enzalutamide may be used in the first-line setting to delay the initiation of chemotherapy in nonmetastatic castration-resistant prostate cancer, as well as metastatic castration-naïve and metastatic castration-resistant disease.[7,67] Apalutamide and darolutamide are also second-generation antiandrogens. Apalutamide is approved for the treatment of nonmetastatic castration-resistant prostate cancer and metastatic castration-naïve prostate cancer.[68] The most common adverse drug reactions associated with apalutamide are fatigue and rash, and apalutamide requires thyroid-stimulating hormone monitoring. The adverse drug reactions of apalutamide and enzalutamide are similar to those of the other antiandrogens, but they both have an increased risk of seizures. Darolutamide is a structurally distinct second-generation antiandrogen, consisting of two pharmacologically active diastereomers,[69,70] which lowers penetration past the blood–brain barrier and results in low binding affinity for γ-aminobutyric acid type A receptors. As a result, darolutamide may cause fewer and less severe adverse drug reactions (eg, less fatigue, but also potentially lower risk for seizures) than enzalutamide and apalutamide despite similar metastasis-free survival rates. Darolutamide is approved for nonmetastatic castration-resistant prostate cancer. The most common antiandrogen-related adverse drug reactions are listed in Table 154-7.

Combined Androgen Blockade

Although up to 80% of patients with advanced prostate cancer will respond to initial hormonal manipulation, almost all patients will progress within 2 to 4 years after initiating therapy.[30] Two mechanisms have been proposed to explain this tumor resistance. The tumor could be heterogeneously composed of cells that are hormone-dependent and hormone-independent, or the tumor could be stimulated by extratesticular androgens that are converted intracellularly to DHT. The rationale for CAB is to interfere with multiple hormonal pathways to completely eliminate androgen action. Antiandrogen therapy should precede, or be co-administered with LHRH agonists, and should be continued for at least 7 days for patients with overt metastases who are at high risk of developing symptoms associated with a testosterone flare that can occur with LHRH agonist therapy alone.[7] Studies of short-term (4-6 months) and long-term (2-3 years) of CAB in those patients with locally advanced disease with intermediate-, high-, and very-high-risk features have all assessed in the neoadjuvant and adjuvant settings, or even concurrently with radiation therapy.[7] Whether the addition of an antiandrogen to ADT is necessary requires further study, but any survival advantage for patients treated with CAB, if present, is small.[72,73] While controversy remains around the appropriate clinical use of CAB, clinicians should recognize that the consequences of financial toxicity and increased side effects must be weighed against modest survival benefit.[72]

Alternative Drug Treatments

Secondary or salvage therapies for patients who progress after their initial therapy depend on what was used for initial management.[7] For patients initially diagnosed with localized prostate cancer, radiotherapy can be used in the case of failed radical prostatectomy. Alternatively, ADT can be used in patients who progress after either radiation therapy or radical prostatectomy.

Abiraterone

Abiraterone is an androgen synthesis inhibitor that targets CYP17A1, which results in a decrease in circulating levels of testosterone.[71] Abiraterone is indicated in patients with metastatic castration-naïve prostate cancer or metastatic castration-resistant prostate cancer.[35] In both metastatic castration-naïve prostate cancer and castration-resistant prostate cancer, abiraterone improves overall survival.[7,74] Hypertension, hypokalemia, and edema may occur due to abiraterone-induced hypoadrenalism that is secondary to CYP17A1 inhibition. Corticosteroids (eg, prednisone) are prescribed concurrently with abiraterone to mitigate these potential adverse drug reactions. Abiraterone is available as the prodrug, abiraterone acetate, and should be taken on an empty stomach as food increases bioavailability by up to 10-fold.[71] A micronized formulation with improved bioavailability is available and can be taken with or without food and at a lower daily dose.[7] Monitoring of liver function tests is recommended at baseline, every 2 weeks for the first 3 months, and then monthly thereafter. Since abiraterone is an inhibitor of CYP2D6, medication profiles should be reviewed for potential drug interactions before initiation of abiraterone therapy.[71]

Chemotherapy

⑧ Chemotherapy with docetaxel improves survival in patients with metastatic castration-naïve and metastatic castration-resistant prostate cancer and is considered a first-line therapy option (see Table 154-8).[7,75–81] Docetaxel 75 mg/m^2 every 3 weeks combined with prednisone 5 mg twice a day was first studied in castration-resistant prostate cancer and shown to improve survival in this setting.[82] Subsequently, docetaxel 75 mg/m^2 every 3 weeks, without prednisone, was studied in the castration-sensitive setting and again shown to improve survival.[83] The most common adverse drug reactions with this regimen are nausea, alopecia, and bone marrow suppression. Other adverse drug reactions of docetaxel include fluid retention (premedication with corticosteroids can minimize) and peripheral neuropathy. Docetaxel is metabolized in the liver; patients with hepatic impairment may not be eligible for treatment with docetaxel because of an increased risk for toxicity (see Table 154-8).[81]

TABLE 154-8

Chemotherapy, Immunotherapy, and Targeted Therapy for Prostate Cancer

Drug	Usual Dose	Toxicities	Hepatic/Renal Adjustments	Monitoring Parameters	Drug Interactions	Administration
Antimicrotubule Agents						
Cabazitaxel	25 mg/m^2 IV every 3 weeks	Fluid retention, constipation, mucositis, myelosuppression, hypersensitivity	Discontinue if ALT >2 times upper limit of normal or patient	CBC weekly during the first cycle, then prior to each treatment, PSA periodically,	Avoid concomitant use of CYP3A4 inducers and inhibitors	Administer IV infusion over 1 hour

			develops jaundice	Monitor for hypersensitivity		
Docetaxel	75 mg/m^2 IV every 3 weeks	Fluid retention, alopecia, mucositis, myelosuppression, hypersensitivity	AST/ALT >1.5 times the upper limit of normal and alkaline phosphatase >2.5 times the upper limit of normal do not administer	CBC with differential, LFTs, bilirubin, alkaline phosphatase, renal function, PSA periodically Monitor for hypersensitivity reactions	Avoid concomitant use of CYP3A4 inhibitors	Administer IV infusion over 1 hour. Premedication with corticosteroids for 3 days beginning the day before
Immunotherapy						
Pembrolizumab	200 mg IV every 3 weeks or 400 mg IV every 6 weeks	Fatigue and immune-mediated (eg, diarrhea, pneumonitis, hepatitis, thyroiditis)	No adjustment needed for baseline renal/hepatic impairment; treat as immune-mediated toxicity if occurs during treatment	CBC, LFTs, renal function, thyroid function, glucose at baseline and during therapy, PSA periodically	Immunosuppressants may decrease therapeutic effect	Administer over 30 minutes
Sipuleucel-T	Each injection contains >50 million autologous CD54+ cells (obtained through leukapheresis) activated with PAP-GM-CSF Dose is given ~ every 2 weeks for 3 total doses	Hypersensitivity, chills, fatigue, fever, headache, myalgias	No dosage adjustment necessary for renal or hepatic dysfunction	No specific laboratory monitoring recommended, PSA periodically	Immunosuppressants may decrease the therapeutic effects of sipuleucel-T	Administer IV infusion over 1 hour. Observe the patient for 30 minutes after the completion of the infusion Premedicate with acetaminophen and an antihistamine 30 minutes prior to administration
Targeted Therapy						
Olaparib	300 mg PO BID	Anemia, nausea,	Reduce dose	CBC at baseline.	Avoid CYP3A4	Administer with

		fatigue, decreased appetite, venous thromboembolism	for moderate renal impairment	and monthly, renal function periodically, PSA periodically	inhibitors and inducers; reduce olaparib dose if using CYP3A4 inhibitor	or without food
Rucaparib	600 mg PO BID	Fatigue, nausea, anemia, hepatotoxicity, decreased appetite	None	CBC at baseline and monthly, PSA periodically	Inhibits CYP1A2, CYP2C19, CYP2C9, and CYP3A4	Administer with or without food
Nuclear Medicine						
Radium-223	50 kBq/kg (1.35 μCi) administered every 4 weeks for 6 injections	Nausea, vomiting, diarrhea, peripheral edema, anemia, lymphocytopenia, thrombocytopenia, and neutropenia	None	CBC should be monitored prior to every injection, PSA periodically	None	Administer radium-223 by slow IV injection over 1 minute

ALT, alanine aminotransferase; AST, asparate aminotransferase; BID, twice daily; CBC, complete blood count; CYP, cytochrome P450; IV, intravenous administration; LFT, liver function test; PAP-GM-CSF, prostatic acid phosphatase granulocyte-macrophage colony-stimulating factor; PO, oral administration; PSA, prostate surface antigen.

Data from References 75-81.

Cabazitaxel is a taxane with demonstrated activity in docetaxel-resistant cell lines and animal models.[80] Cabazitaxel has a lower affinity for the P-gp efflux transporter than docetaxel, which may explain why cabazitaxel is active in the setting of docetaxel resistance. In patients previously treated with docetaxel and prednisone, cabazitaxel 25 mg/m^2 every 3 weeks with prednisone 10 mg daily significantly improved progression-free and overall survival over mitoxantrone and prednisone, but a reduced cabazitaxel dose of 20 mg/m^2 every 3 weeks (with prednisone) has been FDA-approved based on evidence of similar efficacy but better tolerability.[84,85] The addition of carboplatin (AUC 4 mg/mL per min) to cabazitaxel 25 mg/m^2 demonstrated improved progression-free survival versus cabazitaxel alone.[86] As result, guidelines suggest the use of this combination in high-risk metastatic castration-resistant prostate cancer patients who have been pretreated with docetaxel.[7] Neutropenia, febrile neutropenia, neuropathy, and diarrhea are the most significant toxicities. Hypersensitivity reactions may occur and premedication with an antihistamine, a corticosteroid, and an H_2 antagonist is recommended. Cabazitaxel is extensively metabolized in the liver and should be avoided in patients with hepatic dysfunction (Table 154-8).[80] Mitoxantrone plus prednisone has not demonstrated a survival improvement after failure of docetaxel, but remains a palliative therapeutic option, specifically in patients with evidence of visceral metastases and who are not candidates for cabazitaxel or radium-223 therapy.[7]

Immunotherapy

Sipuleucel-T is a novel autologous cellular immunotherapy FDA-approved for the treatment of asymptomatic or minimally symptomatic metastatic castration-resistant prostate cancer.[79] Alternative treatment options for this patient population are secondary hormonal therapy, including antiandrogen therapy, withdrawal of antiandrogen therapy, ketoconazole, abiraterone acetate, enzalutamide, corticosteroids, estrogen, or enrollment on a clinical trial, although none of these options has been shown to improve overall survival. No clinical trials have compared sipuleucel-T to secondary hormonal therapies. Patients treated with sipuleucel-T undergo leukapheresis on day 1 to collect peripheral blood mononuclear cells, the cellular fraction that includes immune effector cells. These cells are incubated with the prostatic acid phosphatase-granulocyte macrophage colony-stimulating factor, or PAP-GM-CSF, fusion protein. Prostatic acid phosphatase, or PAP, is the specific tumor antigen, and granulocyte-macrophage colony-stimulating factor, or GM-CSF, is the immune cell activator. The cellular product is then infused intravenously into the patient on day 3 or 4, providing an autologous infusion of activated cells. Each course of sipuleucel-T consists of three infusions of activated cells, given every 2 weeks. Sipuleucel-T prolongs overall survival by approximately 4 months.[79,87] Adverse drug reactions related to sipuleucel-T are generally mild.

⑨ Somatic and germline HR mutations are common in men with metastatic castration-resistant prostate cancer.[88] Germline genetic testing is recommended in patients with high-risk prostate cancer and/or a relevant family history. Somatic tumor genetic testing is recommended in metastatic disease to identify genetic variants that can be targeted with drug therapy. Pembrolizumab is a monoclonal antibody that inhibits the programmed cell death receptor–1 that is broadly FDA approved for patients with metastatic solid tumors who have documented MSI-H, dMMR by molecular testing or TMB greater than or equal to 10 mut/Mb, who have progressed on prior treatment, and who have no alternative treatment options (Fig. 154-3).[78] Like other immune checkpoint inhibitors, pembrolizumab works by inhibiting signals that lead to T-cell senescence, and thereby increases the immune response to cancer (Table 154-8). MSI-H and dMMR are estimated to occur in approximately 5% to 12% metastatic castration-resistant prostate cancer patients, which makes pembrolizumab a viable treatment option.[88]

Targeted Therapy

⑨ ⑪ PARP enzymes are involved in normal repair of both single-stand and double-strand DNA breaks. The combination of PARP enzyme inhibition by pharmacotherapy and inactivating HR gene mutations results in synthetic lethality that increases genetic instability and induces prostate cancer cell death. Olaparib has been proven effective in metastatic castration-resistant prostate cancer patients harboring pathogenic germline or somatic HR mutations (eg, *ATM*, *BRCA1/2*, *BRCA2*, *BARD*, *BRIP1*, *CDK12*, *CHEK1/2*, *FANCL*, *PALB2*, and *RAD51*) who had progressed on enzalutamide or abiraterone, by improving radiologic progression-free survival.[77] However, pre-specified subgroup analyses suggest that improvement is primarily observed in patients with *BRCA2* mutations.[89] A second PARP inhibitor, rucaparib, obtained FDA accelerated approval in patients with metastatic castration-resistant prostate cancer. Rucaparib has been proven effective in metastatic castration-resistant prostate cancer patients who harbor germline or somatic mutations in *BRCA1/2*, and who have progressed after both second-generation antiandrogens or abiraterone- and taxane-based chemotherapy.[76] In this population, the overall response rate is approximately 44%, a majority of patients (56%) have a response duration >6 months, and progression-free survival is approximately 9 months.[90] Fatigue (including asthenia), nausea, vomiting, diarrhea, anemia, thrombocytopenia, and decreased appetite are the most common toxicities for these two PARP inhibitors. Both olaparib and rucaparib are CYP3A4 substrates. While olaparib doses should be adjusted when concomitantly with CYP3A4 inhibitors, doses of rucaparib do not require adjustments. However, rucaparib inhibits several CYP enzymes (including CYP3A4), and caution should be used with substrates of those enzymes concomitantly with rucaparib (Table 154-8).[76,77]

Nuclear Medicine

Radium-223, an alpha emitter, can be administered to target specific bone metastases with alpha particles in patients with metastatic castration-resistant prostate cancer. Radium-223 administered every 4 weeks improved overall survival by 2.8 months in patients who had already received, were not eligible for, or had declined docetaxel therapy. Improvements in skeletal pain, pain-related outcomes, and quality of life were also significant. Opioid needs were decreased in patients who received radium-223 (36% vs 50%). The most common adverse drug reactions of radium-223 include nausea, diarrhea, vomiting, peripheral edema, and bone marrow suppression.[75,91] Radium-223 may be used in first-, second-, or third-line therapy in patients with metastatic castration-resistant prostate cancer with symptomatic primary bone metastases. Radium-223 has not been approved for use with concomitant abiraterone, second-generation antiandrogens, chemotherapy, immunotherapy, or targeted therapy.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of prostate cancer depends on the grade and the stage of the cancer.[35] When definitive, and curative therapy is attempted, objective parameters should be assessed to evaluate tumor response. These include assessment of the primary tumor size and evaluation of involved lymph nodes through imaging studies, as well as the response of tumor markers, such as PSA, for recurrence or progression. For patients on active surveillance, PSA levels should be checked every 6 months and combined with annual DRE. Following definitive therapy with intent to cure, PSA levels should be checked every 6 to 12 months for the first 5 years and then annually thereafter. For patients at high risk of recurrence, every 3-month PSA testing can be considered.[7] Local recurrence in the absence of a rising PSA may occur, so annual DRE and radiologic studies based on patient-reported symptoms are also performed. In the castration-naïve setting, the response to ADT, radiation, or both dictates monitoring frequency; however, PSA measurement and physical examination every 3 to 6 months can be considered. In the metastatic setting, treatments that directly target the AR signaling axis, traditional cytotoxic chemotherapies, immunotherapies and targeted therapies have demonstrated that they increase survival.

Clinical efficacy is measured with imaging studies (typically CT scans of abdomen/pelvis and bone scans), performance status, symptom scores, weight changes, quality of life, analgesic requirements, and PSA response. However, because PSA is such a robust and reliable biomarker of clinical efficacy in most prostate cancer patients, imaging studies are routine but not performed as often as they are for other solid tumors. When using PSA as a surrogate for disease progression, it is important to consider not only the degree of elevation, but also the velocity at which the marker changes. A rapid PSA velocity has been associated with an increased risk of all-cause mortality, and should warrant consideration of therapeutic intervention.

Monitoring for adverse drug reactions is different for each treatment modality but is similarly important. Monitoring parameters and a review of common adverse drug reactions are provided for hormonal therapies (Table 154-7), as well as chemotherapies, immunotherapies and target therapies (Table 154-8). For pembrolizumab, clinicians and patients should monitor for signs and symptoms of immune-mediated adverse drug reactions (eg, colitis, endocrinopathies, hepatitis, nephritis, or pneumonitis). For sipuleucel-T, clinicians should recognize that traditional markers of benefit (eg, PSA decline or evidence of improvement by imaging studies) may not be present.[7] For orally administered treatments (eg, abiraterone, second-generation antiandrogens, PARP inhibitors, and relugolix), medication adherence is also an important monitoring parameter to evaluate at each clinic visit.

CONCLUSION

Prostate cancer is the most commonly diagnosed cancer in biologic males in the United States (over 20% of the new cases), but the death rate from prostate cancer has declined over the past three decades and only approximately 10% of the cancer-related deaths are attributed to prostate cancer among biologic males in the United States. This shows that for most prostate cancer patients, the disease has an indolent course, and treatment options for localized disease are often effective. While localized prostate cancer can be cured by surgery or radiation therapy, advanced and metastatic prostate cancer are not yet curable. Advanced and metastatic prostate cancer have a consistent pattern of progression, and are fatal. Advances over the past two decades, focusing on improved treatments directly targeting the AR signaling axis, chemotherapies, immunotherapies, and targeted therapies have extended survival for many patients with advanced and metastatic prostate cancer. An understanding of when to initiate early treatment before progression to advanced or metastatic disease continues to evolve (eg, the emergence of novel PMSA-based imaging modalities). Moreover, future research will help clinicians to understand how to combine or sequence treatments for castration-resistant prostate cancer, and continued development of novel therapeutics will prolong survival in patients with the most deadly forms of metastatic prostate cancer (eg, treatment-resistant castration-resistant prostate cancer and neuroendocrine prostate cancer).

ABBREVIATIONS

ADT	androgen deprivation therapy
AJCC	American Joint Committee on Cancer
AR	androgen receptor
BPH	benign prostatic hyperplasia
CAB	combined androgen blockade
CAG	cytosine, adenine and guanine trinucleotide repeat
CYP	cytochrome P450
DHT	dihydrotestosterone
dMMR	deficient mismatch repair
DNA	deoxyribonucleic acid
DRE	digital rectal examination
FDA	United States Food and Drug Administration
FSH	follicle-stimulating hormone
GnRH	gonadotropin-releasing hormone
HR	homologous recombination
LH	luteinizing hormone
LHRH	luteinizing hormone–releasing hormone
MSI-H	microsatellite instability high
PARP	poly-ADP ribose polymerase
PMSA	prostate-membrane specific antigen
PSA	prostate-specific antigen
SRE	skeletal-related event
TMB	tumor mutation burden
TNM	tumor, node, metastasis
US	United States

SELF-ASSESSMENT QUESTIONS

1. MN is a 72-year-old individual who was diagnosed with prostate cancer and is initiated on a hormone agent for the first time for androgen deprivation. Which of the following agents will result in castration levels of testosterone within 7 days?

   A. Leuprolide

   B. Goserelin

   C. Triptorelin

   D. Degarelix

2. BB is a 61-year-old individual with nonmetastatic castration-resistant prostate cancer. He has failed treatment with ADT (leuprolide). He also has several other comorbid diseases including congestive heart failure and diabetes. Which of the following systemic agents is the most appropriate for this patient?

   A. Abiraterone + prednisone + leuprolide

   B. Bicalutamide

   C. Nilutamide

   D. Apalutamide + leuprolide

3. TW is a 68-year-old individual with a history of seizures and prostate cancer who was diagnosed with metastatic disease. He received ADT plus six cycles of docetaxel. His imaging demonstrates progression of disease with bone metastases, and he is complaining of significant back pain. His molecular testing is negative for alterations in homologous recombination genes (eg, *BRCA1/2*) or for MSI-H/dMMR status. Which of the following would you recommend?

   A. Sipuleucel-T

   B. Radium-223

   C. Pembrolizumab

   D. Enzalutamide

4. Which of the following characteristics increases the risk of developing prostate cancer?

A. Asian ancestry

B. Smoking

C. Advanced age (>65 years old)

D. Obesity

5. LJ is a 71-year-old individual with metastatic castration-resistant prostate cancer who has progressed following treatment with ADT + abiraterone and docetaxel. His somatic tumor genetic testing revealed a pathologic ATM mutation, but negative for MSI-H/dMMR status. Which of the following agents could be used to treat LJ based off of his molecular testing results?

A. Rucaparib

B. Olaparib

C. Pembrolizumab

D. Cabazitaxel

6. Denosumab is recommended in patients with prostate cancer for the prevention of SREs while on ADT. Which of the following adverse drug reactions may occur with denosumab?

A. Hypertriglyceridemia

B. Hypertension

C. Hypocalcemia

D. Infusion reactions

7. Which of the following medications should be taken on an empty stomach due to an increase in bioavailability when taken with food?

A. Bicalutamide

B. Abiraterone

C. Enzalutamide

D. Apalutamide

8. GS is a newly diagnosed patient with prostate cancer who will begin ADT with an LHRH agonist. Which of the following are appropriate counseling points for a new patient starting on an LHRH agonist, such as leuprolide?

A. Patients may experience adverse drug reactions, such as a loss in libido, hot flashes, and impotence

B. Patients may experience adverse drug reactions, such as changes in blood pressure

C. Patients may experience adverse drug reactions such as nausea/vomiting, alopecia, and weight loss

D. Patients may experience adverse drug reactions, such as arthralgias, peripheral edema, and seizures

9. SS is a 52-year-old biological male with a history of BPH. His father died of prostate cancer at the age of 74 years. He would like to discuss recommendations for prostate cancer screening, as he is concerned about his risk. Which of the following would you recommend for SS?

A. He should discuss the risks and benefits with his physician, as there are no age-based recommendations for prostate cancer screening

B. Based on his age and family history, he should receive PSA screening annually

C. Based on his age and family history, he should receive DRE screening annually

D. Based on his age and family history, he should undergo genetic testing to characterize his risk of developing prostate cancer

10. A 45-year-old biological male is being seen for the treatment of metastatic castration-resistant prostate cancer. He reports that his father and paternal uncle died of prostate cancer. His paternal grandmother died of breast cancer. He would like to know if he should obtain any genetic testing. What is the most appropriate recommendation for genetic testing for this patient?

    A. He is not eligible for any genetic testing

    B. He should receive germline genetic testing only to determine if he has a heritable cancer risk gene (ie, *BRCA1/2*)

    C. He should receive somatic tumor mutation genetic testing only to determine if he is eligible for therapy with a PARP inhibitor

    D. He should receive both germline and somatic tumor genetic testing to assess heritable cancer risk and determine appropriate therapy

11. JR is a 71-year-old individual who is diagnosed with metastatic castration-naïve prostate cancer and will be initiated on leuprolide. JR has significant disease involvement in his bones, and has bone pain at baseline. What is the most appropriate strategy to prevent bone pain from tumor flare when JR is initiated on an LHRH agonist?

    A. Add bicalutamide

    B. Add abiraterone

    C. Switch leuprolide to goserelin

    D. Discontinue leuprolide and use nilutamide monotherapy

12. Which of the following treatments would be appropriate to treat a patient with locally advanced, nonmetastatic, castration-naïve prostate cancer?

    A. Orchiectomy + leuprolide

    B. Bicalutamide alone

    C. Enzalutamide + degarelix

    D. Degarelix alone

13. Which of the following is the most common site of metastases for prostate cancer?

    A. Brain

    B. Bone marrow

    C. Bone

    D. Heart

14. Which of the following Gleason scores is considered the most aggressive?

    A. 3+3

    B. 4+5

    C. 3+4

    D. 4+4

15. Which of the following regimens is indicated for minimally symptomatic metastatic castration-resistant prostate cancer?

    A. Mitoxantrone

    B. Apalutamide

    C. Radium-223

    D. Sipuleucel-T

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Castration levels are achieved in 7 days or less with degarelix (an LHRH/GnRH antagonist), as compared with 28 days with leuprolide, goserelin, and triptorelin (LHRH agonists) (see the "LHRH/GnRH Antagonists" section).
2. **D.** Apalutamide is indicated for nonmetastatic castration-resistant prostate cancer in combination with androgen deprivation therapy to maintain testosterone levels less than50 ng/dL (1.7 nmol/L). Bicalutamide and nilutamide are first-generation antiandrogens that should not be used alone (without ADT). Abiraterone is not indicated in this setting and would also have the risk of worsening the patient's CHF and diabetes (see Table 154-7).
3. **B.** Radium-223 can be administered to target-specific bone metastases with alpha particles in patients with metastatic castration-resistant prostate cancer. Sipileucel-T is not appropriate given that the patient is symptomatic. He has no biomarkers to predict response to pembrolizumab. Enzalutamide would not be preferred in the setting of seizures (see Fig. 154-3 and Table 154-7).
4. **C.** The majority of prostate cancer cases occur in biological men over the age of 65 years. Geographically, the rate of prostate cancer is lower in Asia, and no increased risk of prostate cancer has been noted in those of Asian ancestry. While obesity and smoking increase the risk of other cancer types, they are not associated with an increased risk of prostate cancer (see Table 154-1).
5. **B.** Olaparib, a PARP inhibitor is approved in patients with a variety of mutations in the DNA repair genes, including *ATM*. Rucaparib is also a PARP inhibitor, but it is only approved in patients with *BRCA1/2* mutations. Pembrolizumab is not indicated in this patient, as they were negative for MSI-H or dMMR. Cabazitaxel is not a targeted therapy, but a cytotoxic chemotherapy (see Fig. 154-3).
6. **D.** Hypocalcemia can occur with denosumab. Patients with normal or low calcium levels should receive oral supplementation with vitamin D and calcium. Since denosumab is administered subcutaneously (versus the bisphosphonates that are given intravenously), infusion reactions are not a concern (see the "Pharmacotherapy: LHRH Aagonists" section).
7. **B.** Abiraterone should be taken on an empty stomach as food increases the bioavailability by 10-fold. Micronized abiraterone avoids this issue and may be administered without respect to meals (see Table 154-7).
8. **A.** LHRH agonists cause adverse drug reactions such as a loss in libido, hot flashes, and impotence. Docetaxel is associated with nausea/vomiting, weight loss, and alopecia. Enzalutamide is associated with arthralgias, edema, and seizures. Abiraterone is associated with changes in blood pressure (see Tables 154-7 and 154-8).
9. **A.** All available guidelines suggest that individuals should have a balanced discussion with their provider about the risks and benefits of prostate cancer screening. There are no age-based recommendations that apply outside of this discussion. If screening is pursued, PSA testing is preferred over DRE. While germline genetic testing is recommended in men with a family history after prostate diagnosis, it is not recommended in this individual who does not yet have prostate cancer and who has a single relative who succumbed to the disease at an advanced age (see the "Screening" section).
10. **D.** The patient should receive BOTH germline and somatic genetic testing based on his family history (multiple first-degree relatives with *BRCA*-related cancers) and the fact that he has metastatic disease that could be treated with targeted therapies, such as PARP inhibitors (see Key Conceptt #10, Genetics and Family History and Fig. 154-3).
11. **A.** LHRH agonists (eg, leuprolide or goserelin) can lead to tumor flare in the initial weeks of therapy before the negative feedback loop is activated to lead to androgen deprivation. Treatment with a first-generation antiandrogen, such as bicaluatmide, for the first 7 days can mitigate that risk (see the "Pharmacotherapy: LHRH Agonists" section).
12. **D.** Locally advanced, non-metastatic castration-naïve prostate cancer can be treated with ADT, orchiectomy, OR ADT + abiraterone. Degarelix, an LHRH/GnRH antagonist, would be appropriate as monotherapy as ADT. A patient who underwent orchiectomy as a means of testosterone suppression would not need the addition of an LHRH agonist, as either alone would be appropriate. Bicalutamide, a first generation anti-androgen, is not recommended as monotherapy for ADT. Enzalutamide is recommended in metastatic castration-naïve prostate cancer but not in the nonmetastatic setting (see Table 154-6).
13. **B.** The bone is the most common site of metastases for prostate cancer (see the "Pathophysiology" section).
14. **B.** A Gleason score of 4+5 for a total score of 9 is considered poorly differentiated and is considered aggressive (see the "Pathophysiology" section).
15. **D.** Sipuleucel-T, an autologous cellular immunotherapy, is indicated for minimally symptomatic metastatic castration-resistant prostate cancer. Mitoxantrone is indicated for those with symptomatic metastatic disease who cannot tolerate other treatments. Apalutamide is indicated for non-metastatic castration-resistant prostate cancer (not metastatic disease). Radium-223 is indicated specifically for bone metastases from prostate cancer (see Table 154-6 and Fig. 154-3).

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 155: Lymphomas

Alexandre Chan; Chia Jie Tan; Shawn Griffin

KEY CONCEPTS

KEY CONCEPTS

① With all stages and risk groups of Hodgkin lymphoma, restaging PET-CT following 8 to 12 weeks of chemotherapy will further guide the patient-specific treatment plan.

② Patients with early-stage Hodgkin lymphoma should be treated with combination chemotherapy with or without involved-site radiation.

③ Combination chemotherapy with doxorubicin (Adriamycin®), Bleomycin, Vinblastine, and Dacarbazine (ABVD) is the primary treatment for patients with advanced-stage Hodgkin lymphoma. Patients with advanced unfavorable disease may be treated with more aggressive regimens, which are associated with a higher risk of secondary malignancies.

④ Some patients with Hodgkin lymphoma will be refractory to initial therapy or will have a recurrence following complete remission. Response to salvage therapy depends on the extent and site of recurrence, previous therapy, and duration of initial remission. High-dose chemotherapy and autologous hematopoietic stem cell transplantation (HSCT) should be considered in patients with refractory or relapsed disease.

⑤ The current classification system for non-Hodgkin lymphoma (NHL) is the World Health Organization (WHO) classification system, which classifies NHLs into specific disease entities, defined by a combination of morphology, immunophenotype, genetic features, and clinical features.

⑥ As compared with Hodgkin lymphoma, the clinical presentation of NHL is more variable because of disease heterogeneity and more frequent extranodal involvement.

⑦ The Ann Arbor staging system correlates poorly with prognosis in NHL because the disease does not spread through contiguous lymph nodes and often involves extranodal sites.

⑧ Several prognostic models have been developed to estimate prognosis in patients with NHL. The International Prognostic Index (IPI) score is a well-established model for patients with aggressive NHL. The Follicular Lymphoma International Prognostic Index (FLIPI) is a similar model for patients with follicular and other indolent lymphomas.

⑨ The clinical behavior and degree of aggressiveness can be used to categorize NHL into indolent and aggressive lymphomas. Patients with indolent lymphoma usually have relatively long survival, with or without aggressive chemotherapy. Although these lymphomas respond to a wide range of therapeutic approaches, few if any of these patients are cured of their disease. In contrast, aggressive lymphomas are rapidly growing tumors and patients have a short survival if appropriate therapy is not initiated. Most patients with aggressive lymphomas respond to intensive chemotherapy and many are cured of their disease.

⑩ Patients with localized follicular lymphoma can be cured with radiation therapy alone. Advanced follicular lymphoma is not curable, and many treatment options are available, including watchful waiting, radiation therapy, anti-CD20 monoclonal antibodies, chemoimmunotherapy, lenalidomide, PI3K inhibitors, an EZH2 inhibitor, CAR-T cell therapy, and high-dose chemotherapy with HSCT.

⑪ Patients with localized aggressive lymphomas can be cured with several cycles of R-CHOP (rituximab, Cyclophosphamide, doxorubicin [Hydroxydaunorubicin], vincristine [Oncovin®], Prednisone) chemotherapy and involved-field irradiation. Patients with bulky stage II, stage III, or stage IV aggressive lymphomas can be cured of their disease with R-CHOP chemotherapy.

⑫ Conventional-dose salvage therapy can induce responses in patients with aggressive lymphomas who relapse, but long-term survival and cure are uncommon. Some patients with aggressive lymphoma who relapse and respond to salvage therapy can be cured with high-dose chemotherapy and autologous HSCT.

BEYOND THE BOOK

BEYOND THE BOOK

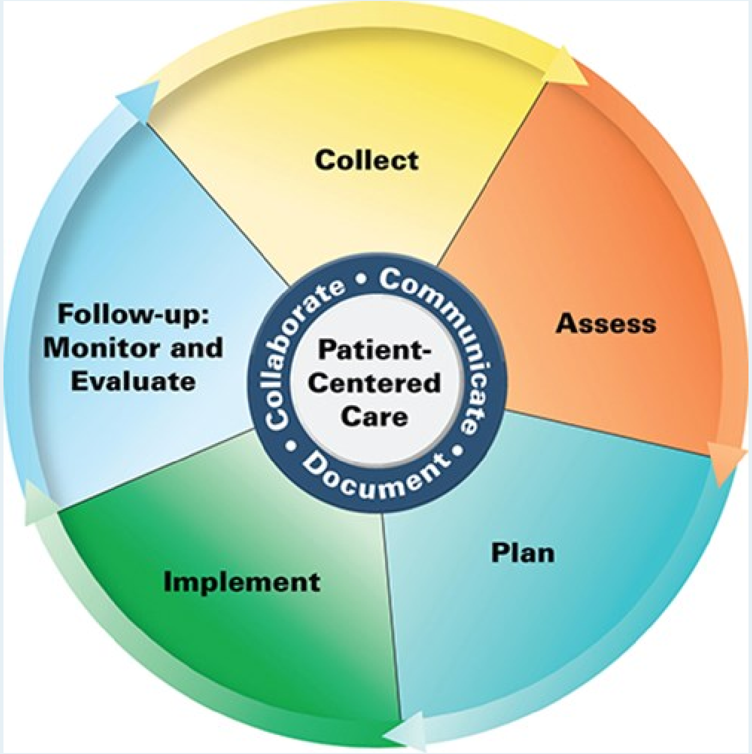
1. Read the patient information sheets from the American Society of Clinical Oncology at Cancer.Net on the diagnosis of Hodgkin and non-Hodgkin lymphoma (https://tinyurl.com/y2rr48nq and https://tinyurl.com/wm8emum). These information sheets briefly describe the various procedures used to diagnose lymphoma and will help students to understand how lymphoma is diagnosed.
2. Search the database of FDA-approved drug products and identify drugs that have been approved by the FDA in the last 12 months for lymphoma. Select one drug and compare the mechanism of action and its role in therapy with existing treatments that carry the same indication. Discuss advantages of this new drug over current therapies and challenges posed when using this new medication.

INTRODUCTION

Lymphomas are a heterogeneous group of malignancies that arise from malignant transformation of immune cells that reside predominantly in lymphoid tissues. They most commonly present as a solid tumor but can sometimes present as circulating tumor cells in peripheral blood. The differing histology of lymphoma cells has led to classification of Hodgkin lymphoma (Reed–Sternberg cells) or non-Hodgkin lymphoma (NHL) (B- or T-cell lymphocyte markers). NHLs are further classified into distinct clinical entities, which are defined by a combination of morphology, immunophenotype, genetic features, and clinical features. Chemotherapy is the mainstay of treatment in patients with lymphoma, especially those with widespread disease. Overall cure rates are high for many subtypes of lymphomas, even when patients present with advanced disease.

PATIENT CARE PROCESS

Patient Care Process for Lymphoma



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnant, smoking history)

- Patient medical history (personal and family)
- Current medications including OTC aspirin/NSAID use, herbal products, dietary supplements
- Objective data
    - Height and weight to calculate body surface area (BSA)
    - Labs include complete blood count (CBC), complete metabolic panel which includes liver function tests, LDH, pregnancy test for women with reproductive potential
    - Baseline assessment of cardiac ejection fraction by ECHO or MUGA if treatment with anthracycline is planned
    - Baseline assessment of pulmonary function (pulmonary function test including diffusing capacity of lungs for carbon monoxide—DLCO) if treatment with bleomycin is planned
    - Lymphoma-specific immunophenotyping, cytogenetics, such as CD20, CD30, t(11:14), t(14;18)
    - Stage and prognostic score (eg, IPS, IPI, FLIPI)

Assess

- Comorbid illnesses that may affect drug therapy selection (baseline neuropathy, CHF, renal or hepatic dysfunction)
- Potential for drug-drug interactions (particularly with oral agents such as idelalisib or ibrutinib)
- Patient's risk of tumor lysis syndrome based on disease, planned therapy, tumor burden, and renal function
- Ability to self-care, family/social support
- Financial challenges—copays, coinsurance, specialty pharmacy medication access
- Birth control and fertility options if the patient is of childbearing age (male and female)
- Emotional status (eg, anxiety, depression)
- Need for central venous access
- Access and availability of eligible clinical trials

Plan*

- Logistics of the treatment plan (inpatient, outpatient, daily oral medication) and monitoring plan
- Patient education (eg, goals and purpose of treatment, treatment schedule, duration/number of treatment cycles, drug-specific information, medication administration)
- Self-monitoring for toxicities, when to seek emergency medical attention
- Referrals to other providers when appropriate (eg, dietician, navigator, behavioral health, integrative health, palliative/supportive care)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Obtain consent for planned treatment

- Use motivational interviewing and coaching strategies to maximize adherence
- Write, order, or review therapy orders to ensure appropriate dosing, supportive care therapies (eg, nausea/vomiting, infection prevention, prevention of hypersensitivity reactions)
- Schedule follow-up (eg, oral therapy medication therapy management, adherence assessment, symptom management)
- Connect patient to resources such as support groups, educational websites, community resources, social worker

Follow-up: Monitor and Evaluate

- Survivorship teaching and follow-up with focus on monitoring for long-term toxicities
- Patient adherence to treatment plan using multiple sources of information
- Imaging studies to be ordered for appropriate follow-up
- Necessary vaccines following stem-cell transplant

**Collaborate with patients, caregivers, and other healthcare professionals.*

HODGKIN LYMPHOMA

Hodgkin lymphoma is one of the most curable forms of cancer. Although initial reports of Hodgkin lymphoma demonstrated the disease to be uniformly fatal, an impressive 80% of patients can be cured today with recommended treatments.[1] Some of the keys to the success of the treatments for Hodgkin lymphoma include the appropriate use of multidrug chemotherapy regimens with differing mechanisms of action and toxicities and treatment with full doses of chemotherapy and on schedule whenever possible. It is also common to use radiation therapy in the treatment schema. However, the success of treatment has not been without cost. The treatment programs are intense, technically demanding, and associated with considerable acute toxicity and long-term complications. The long-term effects, particularly secondary malignancies, account for higher cumulative mortality than Hodgkin lymphoma 15 to 20 years after treatment. Long-term toxicities with standard chemotherapy regimens have been more fully documented in recent years and are shaping future therapies.[2,3]

Hodgkin lymphoma is named after Thomas Hodgkin, who first described seven cases of a mysterious disease of the lymph system in 1832. Although Hodgkin lymphoma was not the first cancer to be described, it was one of the first cancers to have methodical investigational treatments that ultimately lead to successful outcomes.[3]

Since many factors influence the prognosis of patients with Hodgkin lymphoma, treatment plans must be personalized for each patient. The staging for Hodgkin lymphoma uses the Ann Arbor Staging Classification where the “A” refers to the absence of B symptoms, and “B” refers to the presence of B symptoms. Beyond the stage of the disease, certain factors have been associated with a poor prognosis (unfavorable risk). Several research groups have defined these unfavorable factors, and the International Prognostic Score (IPS) is used clinically to predict an individual’s risk of recurrence.

Epidemiology and Etiology

Hodgkin lymphoma represents less than 1% of all known cancers in the United States. About 8,540 new cases of Hodgkin lymphoma were diagnosed in the United States in 2022, and 920 deaths associated with Hodgkin lymphoma will occur during this same period.[4] Hodgkin lymphoma occurs slightly more frequently in males than in females. It exhibits bimodal distribution in industrialized countries; the first peak occurs in young adults and the second smaller peak occurs after the age of 50 years.[2,3] The 5-year overall survival for all stages of Hodgkin lymphoma is about 85%.[1] Death from recurrent Hodgkin lymphoma is less than those from all other causes 15 years after treatment.

The etiology of Hodgkin lymphoma is unknown, but laboratory and epidemiologic evidence supports infectious exposure as a potential cause.[2,3] Studies suggest an increased risk of Hodgkin lymphoma in patients who have been infected with the Epstein-Barr virus (EBV), and many patients experience EBV activation even before the onset of Hodgkin lymphoma. EBV is found in about 40% of all classical Hodgkin lymphoma cases, and it is frequently observed in cases of mixed cellularity and lymphocyte-depleted Hodgkin lymphoma. Reed–Sternberg cells (large, bilobate, multinuclear cells looking like "owl eyes"), the malignant cells in Hodgkin lymphoma, are linked to EBV. Individuals who are immunosuppressed, such as patients with congenital immunosuppression, solid-organ transplant recipients, and human immunodeficiency virus (HIV)-infection, are also at much higher risk of developing Hodgkin lymphoma. Although the risk of developing Hodgkin lymphoma is up to 25-fold greater in patients with HIV, the CD4 level may be low or within the normal range at diagnosis. Almost all cases of Hodgkin lymphoma in HIV-infected individuals are EBV positive and are most commonly the lymphocyte-deplete subtype of Hodgkin lymphoma. Hodgkin lymphoma is not an AIDS-defining illness.

Genetic factors are also associated with an increased risk of Hodgkin lymphoma. The strongest evidence comes from identical twin studies, which show that the unaffected identical twin has almost a 100-fold increase in risk.

Pathophysiology

Hodgkin lymphoma is a clonal malignant lymphoid disease of transformed B-lymphocytes. The malignant cell in Hodgkin lymphoma is the Reed–Sternberg cell, named after Dorothy Reed and Carl Sternberg, who were credited with the first definitive microscopic description of Hodgkin lymphoma.[2] Single-cell polymerase chain reaction and DNA microarray analyses indicate that nearly all classic Hodgkin lymphoma cases and all nodular lymphocyte-predominant Hodgkin lymphomas (NLPHLs) have immunoglobulin gene rearrangements, which indicates a germinal center or postgerminal center of B-cell origin. Interestingly, nearly all Reed–Sternberg cells of classical Hodgkin lymphoma fail to express B-cell specific cell surface proteins.

B-cell transcriptional processes are disrupted during malignant transformation, which prevents B-cell surface marker expression and production of immunoglobulin messenger ribonucleic acid. The normal cellular consequence of failure to express immunoglobulin is apoptosis, but because of alterations in the normal apoptotic pathways, cell survival and proliferation are favored. Reed–Sternberg cells overexpress nuclear factor-κB, which is associated with cell proliferation and antiapoptotic signals. Infections with viral and bacterial pathogens upregulate nuclear factor-κB and consequently are hypothesized to be involved with the etiology of Hodgkin lymphoma.[2] This hypothesis is supported by the presence of EBV in many Hodgkin lymphoma tumors, but not all tumors are associated with EBV. Another signaling pathway, Janus kinase–signal transduction and transcription (JAK–STAT), is also active in Hodgkin lymphoma.[2] As molecular techniques continue to improve, our understanding of the pathophysiology of Hodgkin lymphoma will also improve.

The histopathologic classification of Hodgkin lymphoma has undergone numerous changes over the past three decades. The current classification system is the 2016 World Health Organization (WHO) classification (Table 155-1).[5] This classification divides Hodgkin lymphoma into two major groups: classical Hodgkin lymphoma and NLPHL, which constitute about 95% and 5% of cases, respectively. Classic Hodgkin lymphoma is further divided into four subtypes: nodular sclerosis, mixed cellularity, lymphocyte-depleted, and lymphocyte-rich. The subtypes in these classifications are based on characteristics of the Reed–Sternberg cell, the surrounding cells, and the tissue. Nodular sclerosis has features that make it distinct from the other three subtypes, which represent a continuum of background cellularity, with lymphocyte-predominance being the most cellular and lymphocyte-depletion being the least cellular. Typical immunophenotype for classical Hodgkin lymphoma includes $CD15^+$, $CD30^+$, $PAX\text{-}5^+$ (weak), $CD3^-$, $CD20^-$, $CD45^-$, and $CD79a^-$. NLPHL is separated because of its distinct immunophenotype: $CD15^-$, $CD20^+$, $CD30^-$, and $CD45^+$ (the opposite of classical Hodgkin lymphoma). With the use of extensive staging, sophisticated radiotherapy, and effective combination chemotherapy, the prognostic value of these subtypes is becoming less clear. The true value of understanding these subtypes is likely tied to the pathogenesis of the disease and its potential prevention in the future.

Clinical Presentation: Hodgkin Lymphoma

CLINICAL PRESENTATION: Hodgkin Lymphoma

General

- Most patients with Hodgkin lymphoma have lymph node involvement in the supradiaphragmatic and mediastinal areas.

Symptoms

- Fatigue, malaise, and pruritus.
- About 25% of all patients present with fever, night sweats, and weight loss (ie, B symptoms), and up to 50% of patients with advanced disease.

Signs

- Enlarged lymph node, which may present as painless and rubbery.

Most patients with Hodgkin lymphoma present with a painless, rubbery, enlarged lymph node in the supradiaphragmatic area and commonly have mediastinal nodal involvement. Lymphadenopathy may come and go, but the persistence of lymphadenopathy for more than 2 months warrants evaluation. Hodgkin lymphoma is occasionally diagnosed in an asymptomatic patient who has a mediastinal mass found with chest radiography or another imaging procedure. Asymptomatic adenopathy of the inguinal and axillary regions may be present at diagnosis but is less common (Fig. 155-1).[2,3] Patients can also present with constitutional symptoms (B symptoms) before the discovery of lymph node enlargement, and these symptoms include fever greater than 38°C (100.4°F), drenching night sweats, and weight loss greater than 10% within 6 months of diagnosis. At diagnosis, these symptoms may appear in about 25% of all patients and up to 50% of patients with advanced disease. Patients may also experience other nonspecific symptoms including pruritus, fatigue, and development of pain after alcohol consumption at sites where nodes are involved.[3] Extranodal manifestations, such as bowel or hepatic involvements, are much less common in Hodgkin lymphoma than NHL.[2]

Diagnosis, Staging, and Prognostic Factors

Diagnostic and staging procedures are based on recommendations made at the Ann Arbor and Cotswolds conferences and new scientific advances. The diagnosis and pathologic classification of Hodgkin lymphoma can only be made by review of a biopsy (preferably an excisional biopsy) of the enlarged node by an expert hematopathologist.

In addition to a careful physical examination, routine laboratory tests including a complete blood count, complete metabolic panel to assess renal and hepatic function, lactate dehydrogenase (LDH), and erythrocyte sedimentation rate (ESR) are helpful in treatment planning and aid in prognosis. Pregnancy test and HIV status should be assessed. Computed tomography (CT) scans of the chest, abdomen, and pelvis are routinely performed. Furthermore, positron emission tomography (PET) plays an important role in the initial staging of Hodgkin lymphoma, as it has shown high sensitivity and specificity in the staging of the disease response to treatment.[6] The use of integrated PET-CT has further improved the staging of Hodgkin lymphoma given that it can provide more sensitive and specific imaging as compared with each imaging alone. Bone marrow biopsy is now recommended only in patients with cytopenias and a negative PET.

Staging can be based on clinical or pathologic findings. The clinical stage is based on all noninvasive procedures (history, physical examination, laboratory tests, and radiologic findings), whereas the pathologic stage is based on the biopsy findings of strategic sites (bone marrow, spleen, and abdominal nodes). Patients with extranodal disease (bone marrow, bone, or Waldeyer ring) contiguous to involved nodes are classified with the subscript “E” in the Cotswolds staging system.

The Ann Arbor staging classification, which was developed at the 1970 Ann Arbor conference, has proven to be a good schema. At the Cotswolds meeting in 1989, the Ann Arbor classification was modified to incorporate new diagnostic techniques (eg, CT and magnetic resonance imaging), and the understanding that prognosis is associated with the bulk of the disease and the number of involved nodal sites (Fig. 155-1, Table 155-2).[3] After careful staging, about one-half of patients have localized disease (stages I, II, and II_E) and the remainder have advanced disease (stage III or IV). About 10% to 15% present with metastatic disease (stage IV). Hodgkin lymphoma follows a predictable pattern of nodal spread that is not seen with the NHLs.[3]

TABLE 155-2

The Ann Arbor Staging Classification of Hodgkin Lymphoma

Stage I	Involvement of a single lymph node region or structure (I) or of a single extralymphatic organ or site (I_E)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and one or more lymph node regions on the same side of the diaphragm (II_E). The number of nodal regions involved should be indicated by a subscript (eg, II_2)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by localized involvement of an extralymphatic organ or site (III_E) or by involvement of the spleen (IIIS) or both ($IIIS_E$). III_1: with or without splenic, hilar, celiac, or portal node involvement. III_2: with paraaortic, iliac, or mesenteric node involvement
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node enlargement A—No symptoms B—Fever, night sweats, weight loss (>10%) X—Bulky disease >One-third of the width of the mediastinum >10-cm maximal dimension of nodal mass E—Involvement of extralymphatic tissue on one side of the diaphragm by limited direct extension from an adjacent, involved lymph node region S—Involvement of the spleen CS—Clinical stage PS—Pathologic stage

Patient prognosis is predominately driven by age and amount of disease. Patients older than 65 to 70 years have a lower cure rate than younger patients. The difference in cure rates may be related to the higher prevalence of comorbid diseases and decreased organ function in older patients, which impairs their ability to tolerate intensive chemotherapy. Stage is a dominant factor in predicting survival; patients with limited-stage disease (stages I-II) have a 90% to 95% cure rate, while those with advanced disease (stages III-IV) have only a 60% to 80% cure rate.[2,3]

Seven adverse prognostic factors with similar impact on survival (each factor reduced survival by 7%-8% per year) have been identified through an international collaborative effort. These factors can be combined to generate an IPS that can be used to predict progression-free and overall survival (Table 155-3).[7]

TABLE 155-3

The International Prognostic Factors Project Score for Advanced Hodgkin Lymphoma

Risk Factors
Serum albumin (<4 g/dL [40 g/L])
Hemoglobin (<10.5 g/dL [105 g/L; 6.52 mmol/L])
Male gender
Stage IV disease
Age (≥45 years)
White blood cell (WBC) count (≥15,000 cells/mm^3 [15 × 10^9/L])
Lymphocytopenia (<600 cells/mm^3 [0.6 × 10^9/L] or <8% of WBC count)

Number of Factors	Freedom from Progression*	Overall Survival*
0	84 ± 4	89 ± 2
1	77 ± 3	90 ± 2
2	67 ± 2	81 ± 2
3	60 ± 3	78 ± 3
4	51 ± 4	61 ± 4
≥5	42 ± 5	56 ± 5

Treatment: Hodgkin Lymphoma

Desired Outcomes

The current goal in the treatment of Hodgkin lymphoma is to maximize curability while minimizing short- and long-term treatment-related complications. According to the Surveillance, Epidemiology, and End Results (SEER) database, the 5-year age-adjusted relative survival is greater than 80%.[1] Therefore, the initial treatment goal for all stages of Hodgkin lymphoma is the cure.

General Approach

Combination chemotherapy is the primary treatment modality for most patients with Hodgkin lymphoma. In general, patients of all stages are initially treated with combination chemotherapy for about 8 to 12 weeks (depending on the regimen) and then restaged with PET-CT. Three combination chemotherapy regimens are primarily used for the initial treatment of classical Hodgkin lymphoma: ABVD, BEACOPP (bleomycin, etoposide, doxorubicin [Adriamycin®], cyclophosphamide, vincristine [Oncovin®], procarbazine, and prednisone), and A-AVD (brentuximab vedotin [Adcetris®], doxorubicin [Adriamycin®], Vinblastine, and Dacarbazine). Depending on the initial radiographic response from the restaging, further chemotherapy with or without radiation is planned. For patients with refractory or recurrent disease, salvage therapy consists of multi-agent chemotherapy with or without high-dose chemotherapy and autologous hematopoietic stem cell transplantation (HSCT).[2,3]

Radiation is often an integral part of the treatment plan. Selected patients with early-stage disease (usually nodular lymphocyte-predominant histology) can receive radiation as the only treatment modality, whereas most other patients with early-stage disease may receive chemotherapy and radiation depending on the initial bulk of disease and the response to chemotherapy alone. Although radiation is a local therapy, many patients with advanced disease will also receive radiation therapy to residual or bulky disease sites after chemotherapy. Many different radiation techniques targeting different radiation fields have been used over the last few decades, including involved-field radiation (IFRT), extended-field radiation, subtotal nodal irradiation, and total nodal irradiation. The major concern with radiation therapy is its long-term effects, particularly on organs at risk, such as cardiovascular disease and secondary malignancies that commonly occur in the lung, breast, gastrointestinal tract, and connective tissue.[8] Involved-site radiation therapy (ISRT) and involved-node radiation therapy are now being used as alternatives to the classic IFRT, and both define a smaller field than IFRT. ISRT targets the nodal sites and extranodal extensions involved at diagnosis but spares adjacent uninvolved organs when lymphadenopathy regresses after chemotherapy and ISRT. Additional techniques help refine the volume of radiation delivered to the intended sites such as 4D-CT simulation planning, intensity-modulated radiation therapy, image-guided radiation therapy, and respiratory gating.[9]

Although multiple treatment modalities are used to treat Hodgkin lymphoma, surgery has a limited role regardless of stage. Surgery is important for an accurate diagnosis via excisional biopsy, and on certain other occasions, such as placement of a central line. The following sections will review treatment of early-stage favorable disease, early-stage unfavorable disease, advanced-stage disease, and salvage therapy.

Chemotherapy Regimens

Before the 1960s, the outcome for patients with Hodgkin lymphoma was dismal. Treatment with single-agent therapies or broad radiation fields caused excessive toxicities and few durable responses with advanced disease. The mechlorethamine, vincristine, procarbazine, and prednisone (MOPP) regimen was introduced in the early 1960s and was the initial combination chemotherapy regimen shown to cure advanced Hodgkin lymphoma (Table 155-4). This was a tremendous advance in oncology at that time. MOPP chemotherapy was a mainstay of treatment for patients with stages III and IV advanced Hodgkin lymphoma for many years. However, investigators later learned that MOPP is associated with high rates of sterility and secondary malignancies. The young cohort of Hodgkin survivors would live long enough to endure these consequences. The research focus was then shifted to maintain the high cure rates obtained with MOPP while decreasing the long-term toxicities.

TABLE 155-4

Combination Chemotherapy Regimens for Hodgkin Lymphoma

Drug	Dosage (mg/m^2)	Route	Days
MOPP			
Mechlorethamine	6	IV	1, 8
Vincristine	1.4	IV	1, 8
Procarbazine	100	Oral	1-14
Prednisone	40	Oral	1-14
Repeat every 21 days			

ABVD			
Doxorubicin (Adriamycin®)	25	IV	1, 15
Bleomycin	10	IV	1, 15
Vinblastine	6	IV	1, 15
Dacarbazine	375	IV	1, 15
Repeat every 28 days			
MOPP/ABVD			
Alternating months of MOPP and ABVD			
MOPP/ABV hybrid			
Mechlorethamine	6	IV	1
Vincristine	1.4	IV	1
Procarbazine	100	Oral	1-7
Prednisone	40	Oral	1-14
Doxorubicin	35	IV	8
Bleomycin	10	IV	8
Vinblastine	6	IV	8
Repeat every 28 days			
Stanford V			
Doxorubicin	25	IV	Weeks 1, 3, 5, 7, 9, 11
Vinblastine	6	IV	Weeks 1, 3, 5, 7, 9, 11
Mechlorethamine	6	IV	Weeks 1, 5, 9
Etoposide	60	IV	Weeks 3, 7, 11
Vincristine	1.4[a]	IV	Weeks 2, 4, 6, 8, 10, 12
Bleomycin	5	IV	Weeks 2, 4, 6, 8
Prednisone	40	Oral	Every other day for 12 weeks; begin tapering at week 10
One course (12 weeks)			

BEACOPP (standard-dose)			
Bleomycin	10	IV	8
Etoposide	100	IV	1-3
Adriamycin (doxorubicin)	25	IV	1
Cyclophosphamide	650	IV	1
Oncovin® (vincristine)	1.4[a]	IV	8
Procarbazine	100	Oral	1-7
Prednisone	40	Oral	1-14
Repeat every 21 days			
BEACOPP (escalated-dose)			
Bleomycin	10	IV	8
Etoposide	200	IV	1-3
Adriamycin (doxorubicin)	35	IV	1
Cyclophosphamide	1250	IV	1
Oncovin® (vincristine)	1.4[a]	IV	8
Procarbazine	100	Oral	1-7
Prednisone	40	Oral	1-14
Granulocyte colony-stimulating factor		Subcutaneously	8+
Repeat every 21 days			
A-AVD			
Adcetris® (brentuximab vedotin)	1.2 mg/kg	IV	1,15
Doxorubicin	25	IV	1,15
Vinblastine	6	IV	1,15
Dacarbazine	375	IV	1,15

[a] Vincristine dose capped at 2 mg.

The development of ABVD by Bonadonna et al. at the Milan Cancer Institute about a decade later represents the next important step in the evolution of therapy for Hodgkin lymphoma (see Table 155-4).[10] ABVD was initially shown to be effective in treating MOPP failures and was later compared directly to MOPP in advanced disease, where it produced an 82% complete response rate, as compared to a 67% complete response rate with MOPP. ABVD improved failure-free survival, but no significant differences in 5-year overall survival were noted.[11] Because ABVD was less toxic and provided similar or better outcomes than MOPP, it eventually replaced MOPP as the standard regimen for advanced-stage Hodgkin lymphoma.

In the early 1980s, the Goldie–Coldman hypothesis proposed that chemotherapy resistance was related to spontaneous mutation rates and the development of resistant clones. To test that hypothesis, researchers designed several clinical trials to evaluate the efficacy of alternating non–cross-resistant drug combinations in patients with Hodgkin lymphoma.[12] The initial approach adopted by investigators was to alternate or combine the MOPP and ABVD regimens. When MOPP and ABVD (or doxorubicin [Adriamycin®], bleomycin, vinblastine [ABV]) are combined in a monthly cycle, it is referred to as a hybrid regimen. Besides a potential benefit in efficacy, another potential benefit of alternating or hybrid regimens is the decreased risk of long-term toxicities. In the alternating MOPP/ABVD regimen, the cumulative doses of procarbazine and mechlorethamine are reduced by 50%, and the cumulative doxorubicin dose is reduced by 50%. In the hybrid regimen, the cumulative doxorubicin dose is reduced by 33%, and the cumulative bleomycin dose is reduced by 50%.

Several clinical trials have been performed to evaluate the efficacy of alternating or hybrid MOPP/ABVD regimens. The results of these trials show that alternating and hybrid regimens are superior to MOPP but not to ABVD.[12,13] Another approach evaluated by researchers was the administration of sequential cycles of MOPP and ABVD (MOPP/ABVD). Results of an intergroup trial showed sequential MOPP and ABVD to be inferior to the MOPP/ABV hybrid regimen in terms of response and survival.[13] In another randomized comparison trial of the MOPP/ABV hybrid regimen and ABVD, the complete remission rate, failure-free survival, and overall survival were similar between the two regimens.[14] The latter trial was closed prematurely because of an increased number of treatment-related deaths and secondary malignancies in the patients who received the MOPP/ABV hybrid regimen.

More complex regimens, such as Stanford V and BEACOPP, have been evaluated as alternatives to MOPP or ABVD. Radiation therapy is an integral part of the Stanford V regimen for all patients. The Stanford V regimen generated considerable interest based on the results of phase II trials.[15] Stanford V, ABVD, and an MOPP/ABV hybrid-like regimen (mechlorethamine, vincristine, procarbazine, prednisone, epidoxorubicin, bleomycin, vinblastine, lomustine, doxorubicin, and vindesine [MOPPEBVCAD]) were then compared in a randomized trial to determine the best regimen to support a reduced radiotherapy program.[16] Five-year failure-free and progression-free survival were significantly worse for the Stanford V regimen as compared to the other two regimens. However, no significant differences in overall response rate or 5-year overall or failure-free survival were observed between Stanford V and ABVD in a published randomized trial of patients with advanced Hodgkin lymphoma (E2496).[17] Investigators have speculated that differences in the application of radiotherapy may explain the divergent results in the randomized trials. More pulmonary toxicity occurred in the ABVD group, but other toxicities occurred more frequently in the Stanford V group.

The German Hodgkin Study Group (GHSG) developed the BEACOPP regimens based on the principles of dose density, dose intensity, and mathematical modeling. BEACOPP uses similar drugs as in the cyclophosphamide, vincristine, procarbazine, and prednisone (COPP)/ABVD regimen, but rearranges the drugs in a shorter 3-week cycle. Several different versions of BEACOPP have been developed: standard-dose BEACOPP, escalated-dose BEACOPP, and dose-dense BEACOPP (BEACOPP-14). Granulocyte colony-stimulating factor support is required for the escalated-dose BEACOPP and BEACOPP-14 regimens.

The initial evidence for these regimens focused on patients with advanced or metastatic disease, but subsequent trials have focused on the use of these regimens in early-stage disease.

① With all stages and risk groups of Hodgkin lymphoma, it is current practice to treat with chemotherapy for 8 to 12 weeks and then obtain a restaging PET-CT.[18] This scan is assessed on a PET 5-point scale, also known as the Deauville Criteria based on visual assessment of radiolabeled glucose uptake in involved sites. Score 1 indicates no uptake and can be called a complete response or no measurable disease.[6] For all stages of Hodgkin lymphoma, further treatment is based on the restaging PET/CT results such that residual uptake at the end of chemotherapy would likely indicate the need for ISRT. If a Deauville score of 5 exists after completion of chemotherapy, then a biopsy of the involved area is indicated. With an interval PET/CT scan, every patient's treatment plan is personalized based on the response to treatment.

Classical Hodgkin Lymphoma

Hodgkin lymphoma can initially be divided into two broad classifications: classical Hodgkin lymphoma and NLPHL. Although classical Hodgkin lymphoma can be further divided into pathologic subtypes, the treatments are based on risk factors and the presence of bulky disease regardless of the subtype of classical Hodgkin lymphoma.

Treatment of Early-Stage Favorable Disease

Patients with early-stage favorable disease have stage IA or IIA disease and no adverse risk factors (B symptoms, extranodal disease, bulky disease, three or more sites of nodal involvement, or an ESR of >50 mm/hr [13.9 μm/s]). Extended-field radiation was previously considered the treatment of choice for stages IA and IIA disease. Although most patients were cured of their disease, the radiation is associated with long-term toxicities due to large radiation fields such as heart disease, pulmonary dysfunction, and secondary malignancies.[3]

Combined modality therapy (chemotherapy and radiation therapy) has replaced radiation therapy alone in patients with early-stage favorable disease. With combined modality therapy, both a shorter duration of chemotherapy and newer, more focused radiation techniques (ISRT, others) are used to decrease the long-term toxicities of both.

Clinical trials comparing radiation alone to radiation plus chemotherapy show lower relapse rates in patients treated with combined modality therapy (radiation and chemotherapy), but no change in overall survival because of the availability of effective salvage therapy. Ongoing trials focus on questions such as the optimal number of chemotherapy cycles, the volume of radiation that must be used to obtain optimal patient outcomes, and the role of PET scanning to individualize therapy. Long-term results of clinical trials also suggest that as few as two cycles of Stanford V or ABVD chemotherapy followed by IFRT is sufficient in favorable, early-stage disease patients.[19,20] Different combination chemotherapy regimens have been used in these studies and no one regimen is superior to another.

Clinical trials have also investigated the use of chemotherapy alone to treat low-risk early-stage Hodgkin lymphoma. Long-term results of clinical trials show a lower rate of disease control versus combined modality therapy. Selected patients can be treated with chemotherapy alone if they achieve a complete response following two cycles of chemotherapy, with a total treatment of four cycles of chemotherapy.

Patients with early-stage favorable disease can be treated with two cycles of ABVD alone or plus ISRT or two to four cycles of the Stanford V regimen (doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, and prednisone), followed by a restaging PET-CT scan.[19,20] Depending on the response to the initial chemotherapy, consolidative ISRT is recommended if anything less than a complete response is achieved. With this approach, 5-year progression-free and overall survival rates of more than 90% can be achieved in early-stage favorable disease.

Treatment of Early-Stage Unfavorable Disease

Patients with early-stage disease who have certain features associated with a poor prognosis (B symptoms, extranodal disease, bulky disease, three or more sites of nodal involvement, or an ESR >50 mm/hr [13.9 μm/s]) are defined as having unfavorable disease. Different research groups or clinical trials have different definitions for unfavorable disease. Most groups consider an ESR >50 mm/hr (13.9 μm/s), presence of B symptoms, large mediastinal mass, and more than three affected nodal sites to be unfavorable risk factors. Current guidelines recommend combined modality therapy (combination chemotherapy and ISRT) to reduce the relapse rate and avoid the toxicity associated with extended-field radiation.[18]

Randomized trials show that combined modality therapy reduces the relapse rate in patients with early-stage unfavorable disease. Different chemotherapy regimens and the number of chemotherapy cycles have been compared in clinical trials. In most studies involving early-stage unfavorable disease, ABVD is the comparator arm. ABVD plus 30 Gy [3,000 rad] ISRT remains the standard of care for patients with early-stage unfavorable disease, but the Stanford V regimen plus radiation or BEACOPP for two cycles followed by ABVD for two cycles are both alternatives in select patients. The Stanford V regimen has been studied in several single arm trials[15,21] and comparative trials versus ABVD[17,22] report overall response rates in the 90% range and 5-year overall survival from 88% to 94%. All of these trials included radiation therapy as part of the treatment schema. The GHSG studied the use of a more aggressive regimen of escalated-dose BEACOPP for two cycles followed by ABVD for two cycles versus ABVD for four cycles. Both treatment arms received 30 Gy [3,000 rad] of IFRT. Patients treated with BEACOPP had longer progression-free survival but similar 5-year overall survival as compared with ABVD.[23] Stanford V and BEACOPP are associated with more toxicities than ABVD in early-stage unfavorable Hodgkin lymphoma.[17,24]

② In summary, most patients with early-stage disease will be treated with two to four cycles of ABVD chemotherapy and involved-site radiation. The number of cycles initially administered is based on the classification of favorable versus unfavorable disease. Restaging with a PET-CT after 4 to 12 weeks of chemotherapy further guides the need for more chemotherapy or radiation (ISRT), but most patients with unfavorable disease will require radiation. Clinical trials have demonstrated the utility of PET scans as biomarkers to personalize therapy and minimize the amount of therapy necessary for cure.[6] Despite excellent results from treatment with ABVD and radiation, about 5% of patients do not respond to initial treatment and another 15% of patients will relapse following an initial response.

Treatment of Advanced-Stage Disease

Advanced-stage disease consists of stages III and IV disease. In some studies, stage IIB with a large mediastinal mass or extranodal disease is also considered advanced-stage disease (see Table 155-2). By definition, patients with stages III and IV disease have tumors on both sides of the diaphragm, which almost always precludes the use of radiation alone as a therapeutic modality. Intensive combination chemotherapy is the mainstay of treatment, although some patients will benefit from radiation following chemotherapy. The prognosis of advanced-stage disease is excellent with 5-year overall survival rates ranging from 56% to 90%. Most patients obtain a complete response from their initial treatment. Prognostic factors have been identified and standardized to predict an individual's prognosis, according to the IPS (see Table 155-3).[7]

Patients with advanced-stage Hodgkin lymphoma can be classified into two groups based on the number of prognostic factors present from the IPS (see Table 155-3). Advanced-stage patients with three or fewer poor prognostic factors are considered to have favorable disease and have about a 60% likelihood of being failure-free at 5 years with traditional combination chemotherapy. Advanced-stage patients with four or more poor prognostic factors are considered to have unfavorable disease and a less than 50% likelihood of being failure-free at 5 years with traditional combination chemotherapy. Cures are possible in patients with high-risk disease, but long-term disease control is a more realistic goal for most patients.

Doxorubicin (Adriamycin®), bleomycin, vinblastine, and dacarbazine (ABVD) for decades have continued to be the standard initial regimen for advanced Hodgkin lymphoma in many cancer programs. As discussed in the section "Chemotherapy Regimens," many international randomized large trials have demonstrated ABVD's sustained positive outcomes and lower toxicity profile as compared to other regimens.

The BEACOPP regimens were designed to provide a more aggressive treatment for advanced disease. Several randomized trials have compared BEACOPP to other regimens.[3,25] The GHSG conducted a large randomized comparison of COPP/ABVD (alternating), BEACOPP, or an escalated-dose BEACOPP regimen (HD9 trial).[25] Escalated-dose BEACOPP was the most active regimen in this study, with 10-year freedom from treatment failure at 82% and overall survival at 86%, but this regimen was also associated with more toxicities, including secondary leukemias, and was particularly toxic in older adults.[26] In the HD2000 study, patients with advanced Hodgkin lymphoma were randomized to receive six cycles of ABVD, four cycles of escalated-dose BEACOPP with two cycles of standard-dose BEACOPP, or a third chemotherapy regimen that is not a current standard of care.[27] BEACOPP was superior to ABVD for 5-year progression-free survival (81% vs 68%), but 5-year overall survival was not significantly different between ABVD and BEACOPP. BEACOPP may be superior to ABVD in patients with high-risk advanced Hodgkin lymphoma (IPS ≥3). Higher rates of neutropenia and severe infections were observed with BEACOPP as compared with ABVD. The HD2000 trial also demonstrated a higher risk of secondary malignancy in the BEACOPP versus ABVD arm at 10 years.[28] Finally, GHSG has conducted several trials to evaluate the optimal number and intensity of BEACOPP. The HD12 and HD15 trials are two examples of this research.[29,30] The results of these studies suggest that escalated-dose BEACOPP is superior to ABVD in the treatment of advanced Hodgkin lymphoma, but at the cost of more treatment-related toxicity.

Current treatment options for patients with advanced disease are ABVD or escalated-dose BEACOPP. BEACOPP may be considered in patients less than 60 years old with an IPS of greater than or equal to 4.[30] As with earlier stage disease, combination chemotherapy should be administered for 4 to 18 weeks, depending on the regimen, followed by a restaging PET scan. Based on the residual Deauville score, additional chemotherapy and/or radiation may be administered. The Response-Adapted Therapy in Advanced Hodgkin Lymphoma (RATHL) trial evaluated the use of AVD, ABVD and escalated-dose BEACOPP based on interim PET-CT results after two cycles of ABVD. Those patients with a favorable response on PET-CT received either 4 cycles of ABVD or AVD. There was no difference in 3-year progression-free or overall survival, but there was less pulmonary toxicity in the AVD group due to the omission of bleomycin. Those patients with an unfavorable response on interim PET-CT had treatment intensified to dose-escalated BEACOPP with a 3-year progression-free survival and overall survival of 67.5% and 87.8% respectively.[31]

Brentuximab vedotin is an antibody-drug conjugate (ADC) comprised of an anti-CD30 antibody conjugated by a protease cleavable linker to a potent antimicrotubule agent, monomethyl auristatin E (MMAE). After the ADC binds to CD30 on the cell surface, the ADC-CD30 complex is internalized and then releases MMAE via proteolytic cleavage in the lysosomal compartment. Tubulin binding by MMAE disrupts the microtubule network, which causes apoptotic death of the cancer cells. The A-AVD regimen incorporates brentuximab vedotin instead of bleomycin into the "AVD" backbone (doxorubicin, vinblastine, and dacarbazine). In a large international phase III trial, A-AVD was compared to ABVD in patients with newly diagnosed stage III or IV Hodgkin lymphoma. Toxicities differed in the two arms, where neutropenia, neutropenic fever, and peripheral neuropathy were more common in the A-AVD arm as compared to ABVD. Grade 3 or higher pulmonary toxicity was more common in patients receiving ABVD arm as compared to A-AVD. Of the deaths that occurred in this trial, 11 of the 13 receiving ABVD were associated with pulmonary toxicities, and 7 of the 9 receiving A-AVD were associated with neutropenia. The authors concluded that A-AVD was superior to ABVD, based on the absolute difference of 4.9% in the combined risk of death, progressive disease or incomplete response. Possible candidates for the A-AVD regimen are patients with newly diagnosed disease, no preexisting neuropathy, and a contraindication to bleomycin.[32] The modified 3-year progression-free survival rates were 83.1% in the A-AVD arm and 76% in the ABVD arm.[33]

③ In summary, there are several approaches to the initial treatment of stages III and IV Hodgkin lymphoma. A standard treatment of advanced-stage favorable Hodgkin lymphoma is to administer two cycles of ABVD chemotherapy followed by a restaging PET-CT. If minimal disease is found (Deauville score 1-3), four additional courses of AVD should be given (total of six cycles). If residual disease is suspected (Deauville score 4-5), a switch to escalated-BEACOPP for four cycles should be considered. Escalated-dose BEACOPP or A-AVD for six cycles should be considered for select patients with unfavorable disease. This risk-adapted approach should result in 70% to more than 90% of patients achieving a complete remission and 60% to 80% of patients being cured of their disease. No further treatment is needed for patients who achieve a complete remission (Deauville 1-2) with chemotherapy alone. Patients who achieve a partial remission (Deauville 3-5) should be considered for consolidative radiation to residual sites of disease. As with all stages and risk-groups of Hodgkin lymphoma, if a Deauville score of 5 remains after completion of initial chemotherapy, a biopsy is recommended to determine if refractory disease is present.

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma has been described as more indolent in nature, and has a better prognosis as compared with classical Hodgkin lymphoma. The use of radiation alone for stages I and II NLPHL patients who choose to omit chemotherapy or who cannot tolerate chemotherapy does not adversely affect survival.[18] The disadvantage of radiation therapy alone as compared with combination chemotherapy plus radiation is the higher relapse rate. Patients who relapse after radiation alone (20%-25%) can be successfully salvaged with chemotherapy. If the decision is made to use radiation alone, ISRT is the preferred method. Patients with advanced-stage disease can be treated with combined chemotherapy and radiation therapy. Historically, MOPP and MOPP/ABVD have been used, but these regimens have fallen out of favor much like classical Hodgkin lymphoma. ABVD is frequently used in these patients due to the available evidence to support its use for classical Hodgkin lymphoma, although other regimens, such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), and CVP (cyclophosphamide, vincristine, and prednisone), have been studied. No randomized clinical trials of different chemotherapy regimens have been conducted in NLPHL. NLPHL reliably expresses CD20 and therefore rituximab has demonstrated efficacy in both newly diagnosed and progressive NLPHL. Several phase II trials have reported overall response rates of 90% to 100% with single-agent rituximab.[34,35] Current NCCN guidelines recommend that patients with stage IA or IIA nonbulky disease preferentially be treated with ISRT alone. In select patients with stage IA disease that was completely resected with the excisional biopsy, observation may be an option. Patients with IB, IIB, or advanced disease should receive chemotherapy with or without rituximab and with or without ISRT.[18]

Treatment of Refractory or Relapsed Disease

Refractory disease is defined as disease that persists following initial therapy, including any response less than a complete response. Relapsed disease suggests tumor recurrence following attainment of a complete response. Patients who experience relapsed disease less than 12 months after the completion of therapy have a poor prognosis. The goal of second-line or salvage therapy is still cure. With the increasing use of chemotherapy with or without radiation, regardless of disease extent, the rate of primary refractory disease is decreasing. Many therapeutic options are available for treatment of refractory or relapsed disease, so each patient's treatment should be personalized. The highest survival and cure rates are reported for patients with chemosensitive disease who are medically able to undergo high-dose therapy and autologous HSCT.[36] Since most patients are initially treated with ABVD, doxorubicin should be avoided in salvage chemotherapy regimens if the cumulative dose has reached between 300 and 400 mg/m^2, particularly in those patients who have received mediastinal radiotherapy, because of the higher risk of cardiotoxicity.

The response to salvage therapy depends on the extent and site of recurrence, previous therapy, and duration of initial remission. Patients who relapse after radiation therapy alone have a good chance of being cured with combination chemotherapy, although fewer patients are being treated with radiation alone. High response rates (60%-87%) have been reported with salvage chemotherapy regimens.[2,3] Other patient groups who have a favorable prognosis following salvage therapy include patients who experience a local recurrence in a nonirradiated location and those who relapse more than 1 year after completion of their initial chemotherapy. Patients who experience late relapses can be cured with retreatment with the same chemotherapy regimen, treatment with a different, potentially non–cross-resistant regimen, or high-dose chemotherapy and autologous HSCT.

Patients who have an early relapse (<1 year after treatment) generally respond poorly to standard-dose salvage chemotherapy. High-dose chemotherapy and autologous HSCT are more effective, but also produce a higher risk of treatment-related mortality. Therefore, the choice of salvage treatment should consider the patient's tolerance for a particular set of chemotherapeutic agents and treatment approach (standard-dose chemotherapy vs high-dose chemotherapy and autologous HSCT).

High-dose therapy should be considered in patients who relapse within 12 months of initial remission and in those who are refractory to first-line chemotherapy. Although no single preparative regimen is superior to another, most regimens do not include total-body irradiation because of its potential pulmonary toxicity. Most patients are already at higher risk for pulmonary toxicity because of previous exposure to one or more of the following: bleomycin, thoracic radiation, and nitrosoureas.

Brentuximab vedotin is effective in the relapsed or refractory setting. In a pivotal multicenter phase II study of 102 patients with relapsed or refractory Hodgkin lymphoma after HSCT, 75% and 34% of patients treated with brentuximab vedotin had an objective response and complete remission, respectively.[37] End-of-study results showed that response to brentuximab was durable; patients who achieved complete remission had an overall survival rate of 64% at 5 years and 26% remained in remission with no further anti-cancer therapy after receiving brentuximab.[38] Brentuximab vedotin has also been evaluated as posttransplant consolidation therapy in a phase III trial in 329 patients undergoing autologous HSCT. All patients had a high risk of relapse, defined as disease refractory to initial therapy or relapsed disease less than 12 months from completion of initial therapy with extranodal disease. Patients randomized to receive 16 cycles of brentuximab had significantly longer median progression-free survival (42.9 vs 24.1 months) as compared with placebo.[39] Common toxicities associated with brentuximab vedotin include neuropathy, neutropenia, nausea, and fatigue.[37] Based on these results, brentuximab vedotin received FDA approval for the treatment of classical Hodgkin lymphoma after failure of autologous HSCT or after failure of at least two prior multi-agent chemotherapy regimens in patients who are not candidates for autologous HSCT, and also for patients with classical Hodgkin lymphoma at high risk of relapse or progression as consolidation therapy after autologous HSCT.

Many single-agent and combination regimens can be used as salvage therapy. In this setting, the goal of therapy is disease control and cures are unlikely. Gemcitabine, vinorelbine, and pegylated liposomal doxorubicin (GVD), ifosfamide, carboplatin, and etoposide (ICE) and ifosfamide, gemcitabine and vinorelbine are examples of chemotherapy regimens that include drugs with different mechanisms of action and toxicity profiles than regimens used earlier in therapy. Bendamustine, lenalidomide, and everolimus have shown activity in patients with refractory or relapsed Hodgkin lymphoma.

Immune checkpoint inhibitors, specifically PD-1 (programmed death 1 pathway) inhibitors, are treatment options in refractory Hodgkin lymphoma. Promising results have been reported from phase II trials of heavily pretreated patients. One trial with single-agent nivolumab reported an objective response rate of 87%, with some complete responses; progression-free survival at 24 weeks was 86%.[40] In another phase II trial of nivolumab in 80 patients with classical Hodgkin lymphoma after failure to both HSCT and brentuximab (median of 4 previous therapies), objective responses were achieved in two-thirds of patients.[41] Pembrolizumab, another PD-1 inhibitor, has also been studied in patients with relapsed or refractory disease. In a trial of 31 heavily pretreated patients, a complete response rate of 16% and a partial remission rate of 48% were observed, and the 52-week progression-free survival rate was 46%.[42] A large phase II trial of 210 patients treated with pembrolizumab 200 mg IV every 3 weeks also reported an overall response rate of 69% and a complete response rate of 22%.[43] Based on these results, both nivolumab and pembrolizumab received FDA approval for relapsed Hodgkin lymphoma. Potentially severe graft-versus-host disease has been described in patients who received a checkpoint inhibitor following allogeneic HSCT.[44]

Long-Term Complications

A variety of acute and chronic toxicities may occur as a result of treatment for Hodgkin lymphoma. Long-term complications of radiation therapy, chemotherapy, and combined modality therapy have become more evident as the curability and long-term survival of Hodgkin lymphoma patients have improved.[2,3,18,45] Gonadal dysfunction (including sterility and hypothyroidism), secondary malignancies, and cardiopulmonary diseases are important considerations in the treatment of this malignancy. Almost all men and up to 50% of premenopausal women treated with six cycles of regimens containing alkylating agents become sterile. This is a dose-related phenomenon. For men, even a single dose of nitrogen mustard or chlorambucil can cause sterility, so if fertility is a major concern, ABVD is the best alternative.

The risk of secondary malignancies is increased about threefold in long-term survivors of Hodgkin lymphoma. The risk of developing leukemia carries the highest increase in risk and is seen with radiotherapy, chemotherapy, and chemoradiotherapy. Solid tumors, including breast cancers, gastrointestinal cancers, and lung cancers, are also likely to develop more than 10 years after the completion of treatment. A recently published British cohort study suggested that unlike radiotherapy, which may increase the occurrence of cancer at almost all anatomic sites, chemotherapy is associated with an increased risk of leukemia, NHL, and lung cancer. However, studies that evaluate the risk of secondary malignancies (and other complications) must be interpreted cautiously because many factors probably contribute to the development of secondary malignancies. In addition, much of the long-term complication data are derived from patients who were treated with older regimens and extensive field radiotherapy, which are no longer commonly used in clinical practice. As the field of cancer survivorship continues to grow, more specific recommendations for long-term follow-up are developed. Regular mammograms and breast MRI are recommended starting 10 years following the completion of therapy or at age 40 (whichever is earlier) for females. Patients are at increased risk of lung cancer if they have a smoking history, chest irradiation, and/or alkylating agent exposure. These patients should be considered for low-dose screening chest CT. For cardiovascular monitoring, annual blood pressure monitoring and aggressive management of cardiovascular risk factors are strongly encouraged. Hypothyroidism is reported in about 50% of long-term survivors who received irradiation to this area. Thyroid function tests should be performed annually. Monitoring and follow-up should be personalized after assessing a patient's risks for long-term complications.[18]

NON-HODGKIN LYMPHOMA

The NHLs are a heterogeneous group of lymphoproliferative disorders that affect individuals from early childhood to late adulthood. Advances in molecular biology techniques and our understanding of the human immune system have led to major progress in understanding the pathogenesis and treatment of lymphomas. NHLs are classified into distinct clinical entities defined by a combination of morphology, immunophenotype, genetic features, and clinical features. These differences influence the natural history, approach, and response to treatment. The use of extensive combination chemotherapeutic regimens shows dramatic improvement in survival and cure in patients with a disease that was once considered incurable. The 5-year survival rate for patients with NHL has increased from 48% to 73% over the past 30 years, and the mortality rate actually *declined* from 1997 to 2015.[1,4] Further improvement in survival is anticipated with the continued expansion of our therapeutic armamentarium, including high-dose chemotherapy and targeted therapy.

Epidemiology and Etiology

NHL is the fifth most common cause of newly diagnosed cancer in the United States and accounts for about 4% of all cancers. An estimated 80,470 new cases were diagnosed in 2022, and 20,250 people will die from NHL during this same period.[4] Although the average age of patients at the time of diagnosis is about 67 years, NHL can occur at any age. The incidence rate generally increases with age and is higher in men than in women and in white patients than in black patients.[4] The age-adjusted incidence rate of NHL increased by more than 80% in the United States since the early 1970s, from about 11 cases per 100,000 in 1975 to about 20 cases per 100,000 in 2011 and 2012.[1] The incidence of NHL increased by 3% to 4% from 1975 to 1991, but has finally begun to decline since reaching its peak in 1994. The increased incidence of NHL over the past three decades is second only to melanoma and has been referred to as an epidemic of NHL. Although the increase has been noted particularly among older adults and patients with acquired immune deficiency syndrome (AIDS), much of it cannot be explained by known risk factors.

The etiology of NHL is unknown, although several genetic diseases, environmental agents, and infectious agents are associated with the development of NHL. An increased incidence of NHL is seen in many congenital and acquired immunodeficiency states, supporting the role of immune dysregulation in the etiology of NHL. Patients with congenital immunodeficiency disorders such as Wiskott–Aldrich's syndrome and ataxia telangiectasia, acquired immunodeficiency disorders such as AIDS, and those receiving chronic pharmacologic immunosuppression in the setting of solid-organ transplantation are predisposed to the development of NHL. Autoimmune diseases (Hashimoto's thyroiditis and Sjögren's syndrome) cause chronic inflammation in the mucosa-associated lymphoid tissue (MALT), which predisposes patients to subsequent lymphoid malignancies. Other autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis, are also associated with the development of NHL, but the use of immunosuppressive agents in these diseases makes the pathologic cause less clear.

Certain infections are associated with the development of lymphoma. EBV was discovered in cell lines from tumors of patients with African (endemic) Burkitt lymphoma, and EBV DNA is associated with nearly all cases of endemic Burkitt lymphoma. However, EBV is associated with sporadic Burkitt lymphoma in 15% to 85% of cases. EBV is also associated with posttransplant lymphoproliferative disorders and some lymphomas in patients with AIDS or congenital immunodeficiencies. Extranodal NK-T cell lymphoma is also strongly associated with EBV infection. The nasal-type extranodal NK-T cell lymphoma is more common in East Asia, and less common in Central and South America than in other regions. The human T-cell lymphotropic virus type 1 was the first human retrovirus associated with malignancy. Infection with human T-cell lymphotropic virus type 1, especially in early childhood, is strongly associated with an aggressive form of T-cell lymphoma, known as adult T-cell leukemia/lymphoma. Human T-cell lymphotropic virus type 1 is endemic in parts of southern Japan, Africa, South America, and the Caribbean. In endemic areas, more than 50% of all NHL cases are adult T-cell leukemia/lymphoma. A third virus associated with NHL is human herpesvirus 8 (also referred to as Kaposi sarcoma–associated herpesvirus [KSHV]). This virus was originally isolated from Kaposi sarcoma lesions in AIDS patients. Gastric infection with *Helicobacter pylori*, a gram-negative bacteria that leads to chronic gastritis, is associated with gastric MALT lymphomas. Finally, hepatitis C virus has been associated with splenic and nodal marginal zone lymphomas.

Several physical agents are also associated with the development of NHL. Exposure to herbicides, particularly phenoxyl herbicides, is associated with the development of NHL. These observations may explain why certain occupations, such as farmers, forestry workers, and agricultural workers, are associated with a higher risk of NHL. Exposure to lawn-care pesticides is also increasing in the general population. A higher risk of NHL is also associated with exposure to other chemical solvents and dyes, exposure to radiation from nuclear explosions, and high intake of meats and dietary fats. Smoking or alcohol consumption is not strongly associated with an increased risk of NHL.

Molecular Abnormalities

Chromosomal translocations are a hallmark of many lymphoid malignancies.[46] The presence of these specific translocations can be helpful in the diagnosis and classification of lymphoid malignancies. The mechanisms leading to the translocations are unknown, but they usually involve the antigen receptor loci. In contrast to most myeloid and some lymphoid leukemias, NHLs usually place a structurally intact cellular proto-oncogene under the regulatory influence of highly expressed immunoglobulin or T-cell receptor genes, leading to effects on cell growth, cellular differentiation, or apoptosis. The most common chromosomal translocations involve t(8;14), t(14;18), and t(11;14); each translocation involves the immunoglobulin heavy-chain gene locus on chromosome 14 at 14q32. The translocation t(8;14) that involves c-*MYC*, a well-characterized oncogene associated with malignancy, is implicated in nearly all cases of Burkitt lymphoma. The translocation t(14;18) that involves *BCL*-2, one of several putative B-cell lymphoma-associated oncogenes, is found in about 90% of cases of follicular B-cell lymphomas. The translocation t(11;14) that involves *BCL*-1 is found in about 70% of patients with mantle cell lymphoma (MCL). Another putative B-cell lymphoma-associated oncogene, *BCL*-6, is found in about one-third of diffuse large B-cell lymphomas (DLBCLs).

Although mutations in the *p53* tumor suppressor gene are found in many human neoplasms, such mutations have not been consistently found in patients with lymphoma, which suggests that it may occur late in malignant evolution. Because of their role in the pathogenesis of lymphoma, oncogenes are attractive molecular targets for new and novel therapies.

Pathology and Classification

NHLs are neoplasms derived from the monoclonal proliferation of malignant B or T lymphocytes and their precursors. About 85% to 90% of NHLs in the United States are of B-cell origin. Proliferation of malignant cells replaces the normal cells and architecture of lymph nodes or bone marrow with a relatively uniform population of lymphoid cells. The current classification schemes characterize the NHLs according to the cell of origin (B cell vs T cell), clinical features, and morphologic features. Additional immunohistochemical markers, cytogenetic features, and genotypic characteristics may further classify NHL into subtypes.

⑤ The 2016 WHO classification categorizes lymphoid malignancies into two major categories: B-cell lymphomas and T-cell (and natural killer cell) lymphomas (see Table 155-1).[47] B-cell lymphomas represent about 85% to 90% of all NHLs. Lymphomas within each category can be divided into malignancies of precursor or mature cells. Hodgkin lymphoma and multiple myeloma are recognized as mature B-cell neoplasms. The WHO classification uses the term *grade* to refer to histologic parameters such as cell and nuclear size, density of chromatin, and proliferation fraction, and the term *aggressiveness* to denote clinical behavior of a tumor. This classification scheme includes both lymphomas and lymphoid leukemias, because there is no distinction between the solid and circulating forms of these diseases. The WHO classification includes several previously unrecognized types of lymphomas, and new entities not specifically recognized in the Working Formulation account for about 20% to 25% of the cases.

The WHO classification has broad clinical implications. The WHO Clinical Advisory Committee has agreed that clinical groupings of lymphoid neoplasms into prognostic categories are neither necessary nor desirable because such arbitrary groupings are of no practical value and may be misleading.[48]

Clinical Presentation: Non-Hodgkin Lymphoma

CLINICAL PRESENTATION: Non-Hodgkin Lymphoma

General

- Patients with NHL present with a wide variety of symptoms, depending on the site of involvement and whether tumor involvement is nodal or extranodal.

Symptoms

- About 40% of patients present with fever, night sweats, and weight loss (ie, B symptoms).
- Fatigue, malaise, and pruritus.

Signs

- More than two-thirds of patients present with peripheral lymphadenopathy.

Laboratory Tests

- A complete blood count, tests of renal and liver function, and serum electrolytes should be obtained.
- Serum β_2-microglobulin and LDH levels may be useful as prognostic factors and for monitoring response to therapy.

Other Diagnostic Tests

- Varies depending on the sites of involvement.

⑥ Patients with NHL present with a wide variety of symptoms, depending on the site of involvement and whether tumor involvement is nodal or extranodal. Sites of involvement and dissemination of the malignant cells can sometimes be predicted based on the cell of origin and the tendency of tumors to frequently disseminate to areas where the normal counterparts of the lymphoma cells are located. For example, B-cell lymphomas involve areas of the lymphoid system normally populated by B-lymphocytes such as lymph nodes, spleen, and bone marrow. T-cell lymphomas commonly disseminate to various extranodal sites such as the skin and lungs.[46]

Most patients present with peripheral lymphadenopathy. The lymphadenopathy may be either localized or generalized, and the involved nodes are often painless, rubbery, and discrete, and usually located in the cervical and supraclavicular regions as in Hodgkin lymphoma (see Fig. 155-1). Rapid and progressive lymphadenopathy is more characteristic of aggressive lymphomas. Waxing and waning of lymph nodes, including their complete disappearance and reappearance, is more characteristic of indolent lymphomas. Massive lymphadenopathy can sometimes lead to organ dysfunction. For example, patients with NHL may present with acute renal failure from retroperitoneal adenopathy causing ureteral obstruction or from metabolic abnormalities such as hyperuricemia with uric acid nephropathy.

About 40% of patients with NHL present with fever (temperature >38°C [100.4°F]), weight loss (unexplained weight loss of 10% of body weight over the past 6 months), or night sweats (drenching night sweats). If one or more of these symptoms is present, the patient is noted to have B symptoms, and a

B is added to the stage of disease (discussed in the section “Diagnosis, Staging, and Prognostic Factors” under Hodgkin Lymphoma earlier in this chapter). B symptoms are more commonly observed in patients with aggressive NHLs.

Patients with Hodgkin lymphoma rarely present with extranodal (ie, extralymphatic) disease, but 10% to 35% of patients with NHL have primary extranodal disease at the time of diagnosis. The frequency of extranodal presentation varies dramatically among different subtypes. The most common extranodal sites are the gastrointestinal tract followed by the skin. The liver or spleen may be enlarged in patients with generalized adenopathy. Patients with mesenteric or gastrointestinal involvement may present with signs and symptoms of nausea, vomiting, obstruction, abdominal pain, a palpable abdominal mass, or gastrointestinal bleeding. Patients with bone marrow involvement may have symptoms related to anemia, neutropenia, or thrombocytopenia. Other sites of extranodal disease include the testes and bone. The incidence of solitary brain lymphoma is increasing, especially in patients with AIDS.

Diagnosis, Staging, and Prognostic Factors

As with Hodgkin lymphoma, the diagnosis of NHL must be established by pathologic review of tissue obtained by biopsy.[46,49,50] The preferred procedure is an excisional biopsy, where the entire involved lymph node is removed for review by an experienced hematopathologist. This procedure should be done carefully to prevent distortional artifact of the architecture, which could lead to an inaccurate diagnosis. Needle biopsy of the node can sometimes provide adequate tissue for pathologic diagnosis if an excisional biopsy cannot be performed. When adenopathy is not present, diagnosis may be established by biopsy of cutaneous lesions, bone marrow biopsy and aspiration in patients with unexplained myelosuppression, liver biopsy in patients with hepatomegaly or elevated liver function tests, or biopsy of involved extranodal organs such as bone, Waldeyer’s ring, lung, and testis.

After the diagnosis is established, further workup is required to determine the extent of involvement.[46,49,50] Clinical staging always begins with a thorough history and physical examination. Patients should be questioned about the presence or absence and extent of fever, night sweats, and weight loss. A detailed history of lymphadenopathy should also be obtained, including when and where the lymph nodes were first noted, and their rate of growth. A complete physical examination is performed to assess the extent of disease involvement, with special attention given to all nodal areas (see Fig. 155-1). All patients should have a complete blood count, serum chemistries including liver and renal profiles. Lumbar puncture to evaluate the cerebrospinal fluid is recommended in patients who have histologic types of lymphoma that often spread to the CNS.

Imaging studies are important in the staging workup. In the most recent recommendations, PET-CT is the gold standard for assessment of essentially all lymphoma histologies, except chronic lymphocytic leukemia/small lymphocytic lymphoma, lymphoplasmacytic lymphoma/Waldenstrom’s macroglobulinemia, mycosis fungoides, and marginal zone NHLs, unless there is a suspicion of aggressive transformation.[50] The total metabolic tumor volume at diagnosis may play a prognostic role.[51] Magnetic resonance imaging is of limited usefulness in the staging of NHL. Gallium scans are sometimes used as part of the staging workup. Other tests, such as liver-spleen scan, bone scan, upper gastrointestinal series, and IV pyelogram, are sometimes useful in patients with organ symptomatology or serum chemistry abnormalities.

The likelihood of bone marrow involvement varies among the different histologic types of lymphoma (Table 155-6). In the NCCN guidelines, bone marrow biopsy with or without aspirate is included in the essential workup for all lymphomas. Although PET-CT scans are as sensitive as bone marrow biopsy in the identification of bone marrow involvement in certain subtypes of NHL including DLBCL, bone marrow biopsy remains preferable for identifying bone marrow involvement in indolent lymphomas such as follicular lymphoma.

The Ann Arbor staging classification developed for the clinical staging of Hodgkin lymphoma is also used to stage patients with NHL (see Table 155-2). After completion of the staging workup, most patients will be found to have advanced disease (stages III and IV). The frequency of localized disease at the time of diagnosis varies depending on the histologic type of lymphoma (see Table 155-5). Stage is a more important prognostic factor in Hodgkin lymphoma than in NHL.

TABLE 155-5

Clinical Characteristics of Patients with Common Types of Non-Hodgkin Lymphomas

Disease	Median Age (Years)	Frequency in Children	% Male	Stage I/II vs III/IV (%)	B Symptoms (%)	BM Involvement (%)	GI Tract Involvement (%)	5 Year Survival (%)
B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma	65	Rare	53	9 vs 91	33	72	3	51
Mantle cell lymphoma	63	Rare	74	20 vs 80	28	64	9	27
Extranodal marginal zone B-cell lymphoma of MALT type	60	Rare	48	67 vs 33	19	14	50	74
Follicular lymphoma	59	Rare	42	33 vs 67	28	42	4	72
Diffuse large B-cell lymphoma	64	≈25% of childhood NHL	55	54 vs 46	33	16	18	46
Burkitt lymphoma	31	≈30% of childhood NHL	89	62 vs 38	22	33	11	45
Precursor T-cell lymphoblastic lymphoma	28	≈40% of childhood NHL	64	11 vs 89	21	50	4	26
Anaplastic large T-/null cell lymphoma	34	Common	69	51 vs 49	53	13	9	77
Peripheral T-cell non-Hodgkin lymphoma	61	≈5% of childhood NHL	55	20 vs 80	50	36	15	25

⑦ The Ann Arbor system emphasizes the distribution of nodal disease sites because Hodgkin lymphoma usually spreads through contiguous lymph nodes and does not involve extranodal sites. But NHL is a disease with tremendous heterogeneity that does not spread through contiguous lymph nodes and often involves extranodal sites. As a result of these clinical differences between Hodgkin lymphoma and NHL, Ann Arbor stage correlates poorly with prognosis.

⑧ This lack of accuracy with the Ann Arbor staging system in NHL has led to several international projects to develop prognostic models for the most common types of NHLs—DLBCLs and follicular lymphomas. The International Non-Hodgkin Lymphoma Prognostic Factors Project was based on more than 2,000 patients with diffuse aggressive lymphomas treated with an anthracycline-containing combination chemotherapy regimen in the United States, Europe, and Canada.[52] The Project identified five risk factors that correlated with low complete response rate to chemotherapy and poor survival, and a subgroup analysis found three specific risk factors correlated with low complete response rate to chemotherapy and poor survival in patients 60 years old and above (Table 155-6). It is unclear whether the effect of serum LDH level is related to a tumor or a host event. LDH likely measures cellular catabolism (the enzyme is released from injured cells) or the product of tumor burden and proliferation. Because each of the factors has about the same impact (eg, relative risk) on prognosis, the number of adverse risk factors is summed to provide the IPI. Patients could therefore have a score of 0 to 5. For patients older than or equal to 60 years, a simplified IPI score can be determined based on Ann Arbor stage, serum LDH level, and performance status.

TABLE 155-6

Risk Factors According to the International Non-Hodgkin Lymphoma Prognostic Factors Project

All Patients	Patients ≤60 years of age
Age >60 years	Abnormal LDH level
Abnormal LDH level	Performance status ≥2
Performance status ≥2	Ann Arbor stage III or IV
Ann Arbor stage III or IV	
Extranodal involvement ≥2 sites	

LDH, lactic dehydrogenase.

Data from Reference 52.

It is important to periodically reevaluate prognostic factors as prognosis improves as a result of more effective therapy. The IPI was based on patients treated from 1982 to 1987 with anthracycline-based combination chemotherapy; none of the patients received rituximab. Therefore, an enhanced IPI (NCCN-IPI) was developed to stratify newly diagnosed DLBCL patients based on their clinical features (age, normalized LDH, sites of involvement, Ann Arbor, and ECOG performance status) in the rituximab era.[53] Through an independent validation, the NCCN-IPI was shown to discriminate patients in the low- and high-risk subgroups better than the IPI.

Although the IPI is often used to predict prognosis in patients with other NHL subtypes, the IPI has several shortcomings when applied to patients with indolent lymphomas. Because only patients with diffuse aggressive lymphomas were used to develop the IPI system, some important prognostic factors may have been missed. Furthermore, the IPI system has limited discriminating power in follicular lymphoma because only about 10% of patients are categorized as high-risk in the IPI system. To address these concerns, an international cooperative study was designed to develop a prognostic model similar to the IPI in patients with follicular lymphoma. The results of that study, which was based on more than 4,000 patients with follicular lymphoma diagnosed between 1985 and 1992, identified five factors that correlated with poor survival (Table 155-8).[54] Analogous to the IPI, the number of adverse risk factors is summed to provide the Follicular Lymphoma International Prognostic Index (FLIPI). FLIPI had higher discriminating power among groups as compared with the IPI system. Table 155-8 shows the number of risk factors stratified with FLIPI. The survival data from FLIPI, however, may not reflect current treatment results because none of the patients in the cohort used to derive the FLIPI were treated with rituximab. In an updated prognostic model (FLIPI-2) derived from patients with newly diagnosed follicular lymphoma treated with rituximab-containing chemoimmunotherapy regimens, age older than 60 years, low hemoglobin level (<12 g/dL [120 g/L; 7.45 mmol/L]), longest diameter of the largest lymph node more than 6 cm, abnormal β_2-microglobulin levels and bone marrow involvement were identified as adverse risk factors. FLIPI-2 was highly predictive of treatment outcomes and separated patients into three distinct risk groups: low-risk (0 factors), intermediate-risk (1 or 2 factors), and high-risk (≥3 factors). Three-year progression-free survival was 91%, 69%, and 51%, and overall survival was 99%, 96%, and 84% in low-, intermediate-, and high-risk patients, respectively.[55]

Although IPI and FLIPI are clinically useful tools to estimate prognosis, the factors used to calculate these scores probably represent clinical surrogates for the biologic heterogeneity among NHLs and many researchers are interested in determining the prognostic importance of certain phenotypic and molecular characteristics of NHLs. For example, molecular markers of apoptosis, cell-cycle regulation, cell lineage, and cell proliferation are being evaluated as potential prognostic factors.[56]

Gene expression profiling with microarrays may also correlate with survival. Using gene expression profiling, investigators identified at least two molecularly distinct types of DLBCLs based on gene expression patterns indicative of different stages of B-cell differentiation: germinal center B-cell–like (GCB) and activated B-cell–like (ABC), with 10% to 15% being unclassifiable.[56,57] The GCB subtype of DLBCL probably arises from normal germinal center B-cells while the ABC subtype may arise from postgerminal center B-cells. Many oncogenic pathways are different for the GCB and ABC subtypes, and these differences may lead to the development of targeted therapies for each subtype.[56] Patients with the germinal center B-cell profile had significantly better overall survival independent of IPI score after treatment with cyclophosphamide, doxorubicin [hydroxydaunorubicin], vincristine (Oncovin®), prednisone (CHOP), or CHOP-like chemotherapy. In a published study of patients with DLBCL treated with either CHOP or rituximab and CHOP (R-CHOP), Lenz et al. identified several gene expressions signatures that predicted survival in both CHOP and R-CHOP cohorts: GCB, stromal-1, and stromal-2.[58] The GCB and stromal-1 signatures were associated with a favorable prognosis while the stromal-2 signature was associated with an unfavorable prognosis. The stromal-1 signature reflects extracellular matrix deposition and histiocytic infiltration whereas the stromal-2 signature reflects tumor blood vessel density. It is speculated that DLBCLs that express the stromal-2 signature may respond to antiangiogenic agents.

Another important but rare molecular subtype is double-hit NHL, which is now classified by WHO as high-grade B cell lymphoma with MYC gene arrangement and BCL2 or BCL6 translocation. If all three are rearranged, it is referred to as triple-hit NHL. Patients with double-hit or triple-hit NHL have a poor prognosis, with a median overall survival that is 4 to 6 months even with highly aggressive chemotherapy.[59] Some lymphoma experts suggest that patients with double-hit NHL should be treated with more dose-intensive regimens.[56] Besides double-hit NHL, a more common molecular subtype is double-expressor NHL, accounting for 20% to 30% of DLBCL cases. Unlike double-hit NHL, patients with double-expressor lymphoma co-express MYC and BCL2 proteins without underlying chromosomal rearrangements. Double-expressor NHL is associated with a worse prognosis than other DLBCLs, but it has slightly better outcomes than double-hit NHLs. More intensive treatment regimens are also being evaluated in patients with double-expressor NHL.[60]

Two molecularly distinct profiles of follicular lymphoma have been identified. The first includes genes encoding for T-cell markers and genes highly expressed in macrophages, and the second includes genes that are preferentially expressed in macrophages, dendritic cells, or both.[61] Patients with the first molecular signature have a more favorable outcome than those with the second signature. These results suggest that molecular classification of NHL based on gene expression may allow the identification of clinically significant subtypes.

Treatment: Non-Hodgkin Lymphoma

Desired Outcomes

The primary goals in the treatment of NHL are to relieve symptoms, cure the patient of the disease whenever possible, and minimize the risk of serious toxicities. The treatment strategy depends on many factors, including the patient's age, concomitant disease, disease type, stage of disease, site of disease, and patient preference.

General Approach

⑨ Historically, the clinical behavior and degree of aggressiveness are used to describe NHLs. Indolent lymphomas, which make up about 25% to 40% of all NHLs, are characterized by their slow-growth behavior. Patients with indolent lymphoma usually have a relatively long survival (measured in years), with or without aggressive chemotherapy. Although these lymphomas respond to a wide range of therapeutic approaches, there is no convincing evidence of a survival plateau, which indicates that patients are rarely cured of their disease. In contrast, aggressive lymphomas, which make up about 60% to 75% of all NHLs, are characterized by rapid growth rate and short survival (measured in weeks to months) if appropriate therapy is not initiated. Despite their more aggressive nature, many patients with aggressive lymphomas who respond to chemotherapy can experience prolonged disease-free survival and some are cured of their disease. Therefore, the terminology for the NHLs represents a paradox, where "indolent" is bad and "aggressive" is good in terms of the likelihood of cure.

Therapeutic approaches to NHL include radiation therapy, chemotherapy, and biologic or targeted agents. The role of radiation therapy in the treatment of NHL differs from its role in the treatment of Hodgkin lymphoma. Although the disease responds to radiation therapy, only a small percentage of patients with NHL present with truly localized disease that can be treated with local or regional radiation therapy. Radiation therapy is used more commonly in advanced disease, primarily as a palliative measure to control local bulky disease.

Effective chemotherapy for NHL ranges from single-agent therapy in indolent lymphomas to aggressive, complex chemotherapy regimens in aggressive lymphomas. The most active agents used in the treatment of NHL include the alkylating agents (eg, cyclophosphamide, chlorambucil), bleomycin, doxorubicin, purine analogs, etoposide, methotrexate, vincristine, and corticosteroids (eg, prednisone, dexamethasone). The most aggressive chemotherapy approaches are dose-dense chemotherapy or high-dose chemotherapy followed by autologous or allogeneic HSCT.

B-cell lymphomas have served as a model for immunotherapy with monoclonal antibodies for more than 20 years, beginning with the successful use of custom-made monoclonal antibodies targeted against the idiotype present on the patient's cancer cells.[62] These encouraging results lead to the development of monoclonal antibodies against a more generic target, a molecule on the surface of B cells that would be present on tumor cells. One potential target, the CD20 molecule, is present only on cells in the B-lymphocyte lineage. It is expressed on the surface of both normal and malignant B cells, but not on other normal tissues. Rituximab (Rituxan®) is a chimeric monoclonal antibody directed at the CD20 molecule. Its antitumor activity is mediated through complement-dependent cytotoxicity, antibody-dependent cytotoxicity, and induction of apoptosis.[62] With the availability of monoclonal antibodies and radioimmunoconjugates for the therapy of lymphoma, nearly all patients with NHL will receive one or more biologic agents during the course of their disease.

Objective response to therapy for NHL should be defined according to the Lugano classification. The Lugano classification was established at the 12th International Conference on Malignant Lymphoma 2013. The revised guidelines describe criteria for response (eg, complete response, partial response, and stable disease) and emphasize the role of PET-CT and CT in the assessment of response in lymphoma treatment. PET-CT is recommended in FDG-avid histologies such as Hodgkin lymphoma, DLBCL, and follicular lymphoma while CT is advised for other lymphomas with low or variable FDG-avidity.[50]

Appropriate therapy for NHL depends on the patient's age, histologic type, stage of disease, site of disease, presence of adverse prognostic factors (as measured by IPI or FLIPI score), and patient preferences. In general, treatment of lymphoma can be divided into limited disease and advanced disease. Limited disease includes those patients with localized disease (Ann Arbor stages I and II). Advanced disease is defined as all Ann Arbor stage III or IV patients, and also frequently includes Ann Arbor stage II patients with poor prognostic features (see Tables 155-6 and 155-7).[52,54]

TABLE 155-7

Risk Factors According to the Follicular Lymphoma International Prognostic Index

All Patients
Age >60 years
Ann Arbor stage III or IV
Number of nodal sites ≥5
Abnormal lactate dehydrogenase level
Hemoglobin <12 g/dL (120 g/L; 7.45 mmol/L)

Risk Group (% of Patients)	Number of Risk Factors
Low (36)	0-1
Intermediate (37)	2
High (27)	≥3

The following section discusses the clinical characteristics and therapy of the most common disease entities.

Follicular Lymphomas

The combined group of follicular lymphomas makes up the second most common histologic type of NHL in the United States, comprising about 20% to 25% of all new NHLs diagnosed in western countries.[61] The WHO classification includes criteria for grading follicular lymphoma based on the number of centroblasts per high-power field: grade 1 to 2 (0-15 centroblasts/high-power field) and grade 3 (>15 centroblasts/high-power field).[5] The clinical behavior and treatment outcome of grades 1 and 2 follicular lymphoma are similar, and they are usually treated as indolent lymphomas. The current WHO classification subdivides grade 3 follicular lymphoma into grades 3A and 3B. The WHO recommends that grade 3A follicular lymphoma should be treated in the same way as low-grade follicular lymphoma, whereas grade 3B should be treated in the same way as an aggressive lymphoma.

Follicular lymphomas tend to occur in older adults, with a slight female predominance (see Table 155-5). Most patients have advanced disease at diagnosis, but about 25% to 33% of patients have localized disease (clinical stage I or II) at diagnosis.[63] Extranodal disease, bulky disease, and B symptoms are uncommon features at diagnosis. Most patients with follicular lymphoma have chromosomal translocation t(14;18) at the time of diagnosis.

The clinical course is generally indolent, with median survivals of 8 to 10 years. But the natural history of follicular lymphoma can be unpredictable. Spontaneous regression of objective disease has been noted in as many as 20% to 30% of patients. There is also a high conversion rate of follicular lymphoma to a more aggressive histology over time that steadily increases after diagnosis and reaches about 30% at 10 years.[64] At autopsy, most patients with follicular lymphoma have some evidence of DLBCL. Patients with transformed indolent lymphoma should be treated in the same way as patients with an aggressive lymphoma.

Most patients have dramatic responses to initial therapy, and their disease course is characterized by multiple relapses, with responses to salvage therapy becoming progressively shorter after every relapse, eventually leading to death from disease-related causes. This pattern of constant relapses over time without evidence of a survival plateau and the failure of randomized controlled trials to show a survival benefit with aggressive chemotherapy led to the conclusion that therapy does not prolong overall survival or cure patients of their disease. However, the use of biologic agents, particularly rituximab, has changed the natural history of follicular lymphoma. In a study of patients enrolled in Southwest Oncology Group (SWOG) trials over more than 20 years, patients treated with CHOP and a monoclonal antibody had a significantly longer 4-year overall survival than those treated with CHOP alone (91% vs 69%).[65] With advances in therapeutics, the life expectancy of patients with follicular lymphoma has correspondingly increased. However, lymphoma is still the leading cause of death among patients diagnosed with follicular lymphoma in the rituximab era, especially among those patients experiencing disease transformation.[66]

Certain subsets of patients with follicular lymphoma have a much better or worse prognosis. The natural history of follicular large cell lymphoma (ie, grade 3 follicular lymphoma) is similar to that of other aggressive lymphomas and that treatment with intensive combination chemotherapy regimens may result in long-term disease-free survival, including a possible plateau in the survival curve.[67] The recent development of the FLIPI prognostic model should help clinicians to identify patients in different prognostic groups based on disease characteristics at the time of diagnosis.[54] Patients who are predicted to have a poor prognosis (ie, high-risk) could then be offered aggressive or experimental therapy, while those who are predicted to have a good prognosis (ie, low-risk) would be treated with standard therapy, avoiding unnecessary toxicity.

Treatment of Localized Disease (Stages I and II)

Radiation therapy is the standard treatment for early-stage follicular lymphoma. Involved-field, extended-field, and total nodal irradiation have been used. Carefully staged patients with either stage I or contiguous stage II disease treated with radiation therapy alone can achieve disease-free survival rates of 40% to 50% and overall survival rates of 60% to 70% at 10 years.[67] Late relapses are uncommon; only 10% of patients who reached 10 years without relapse subsequently experienced a recurrence.

Chemotherapy is not usually given in most patients with localized follicular lymphoma, but it may be helpful in some patients with high-risk stage II disease (eg, multiple sites of involvement or bulky disease).[68]

⑩ About 40% to 60% of patients with clinical stage I or II follicular lymphoma are cured of their disease with radiation therapy alone.[49] Most centers use radiation at a dose of 30 to 40 Gy (3,000-4,000 rad) to either involved (ie, local) or regional fields, which would consist of irradiation to the involved nodal region plus one additional uninvolved region on each side of the involved nodes. Extended-field irradiation is not usually used because of the absence of a survival benefit and possible increased risk of secondary malignancies. In addition, previous use of extended-field irradiation compromises the ability of that patient to receive subsequent chemotherapy. The current NCCN guideline states that locoregional radiation therapy is preferred for most patients with early-stage follicular lymphoma.[49] Anti-CD20 antibodies, in combination with chemotherapy, are also listed as an option.

Treatment of Advanced Disease (Stages II Bulky, III, and IV)

The management of stages II Bulky, III, and IV indolent lymphomas remains controversial because until recently, no therapeutic approaches had been shown to prolong overall survival despite the high complete remission rates to initial therapy. More than 80% of patients with stage III or IV follicular lymphoma are alive at 5 years, and the median survival ranges between 7 and 10 years.

Although complete remission can be achieved in 50% to 80% of patients with various treatments, the median time to relapse is usually only 18 to 36 months. About 20% of patients who have a complete response remain in remission for longer than 10 years. After relapse, patients are retreated and high remission rates can be achieved. Unfortunately, response rates and duration of response decrease with each retreatment.

Several different approaches can be used to treat follicular lymphoma. Carefully selected patients may receive no initial therapy followed by chemoimmunotherapy or single-agent anti-CD20 therapy, or radiation therapy when treatment is needed. Candidates for the conservative approach are usually older, asymptomatic, and have minimal tumor burden. Patients with symptoms, extensive extranodal involvement, bulky disease, cytopenia due to bone marrow involvement, splenomegaly and steady progression over at least 6 months, or impaired end-organ function at the time of diagnosis are not candidates for conservative treatment. Patients who respond to induction therapy may receive maintenance therapy with single-agent anti-CD20 therapy.

At the time of relapse, many of the same treatment options are available, and the following factors must be considered: age, symptomatic status of the patient, tumor burden, rate of regrowth (based on previous assessment of active disease sites), presence or absence of characteristics suggesting transformation or biologic progression, prior therapy, degree and duration of response to prior therapy, availability of clinical trials, and patient preferences.[49]

Watch-and-Wait

Because there are no convincing data that standard treatment approaches have improved survival, some clinicians have adopted a "watch-and-wait" approach for asymptomatic patients where therapy is delayed until the patient experiences systemic symptoms or disease progression such as rapidly progressive or bulky adenopathy, anemia, thrombocytopenia, or disease in threatening sites such as the orbit or spinal cord.[68] In a randomized study of asymptomatic patients with indolent lymphomas (mostly follicular), patients who underwent watchful waiting had similar cause-specific and overall survival as compared with those who received immediate chlorambucil.[69] With a median length of follow-up of 16 years, about 17% of patients who were randomized to the watchful waiting group died of other causes without receiving chemotherapy and an additional 9% are alive and have not yet had chemotherapy. Due to the frequent use of rituximab in current clinical practice, a recent study has evaluated whether the use of the "watch-and-wait" approach is more effective than the use of rituximab to delay the need for chemotherapy or radiotherapy in patients with advanced-stage, low tumor burden follicular lymphoma. Immediate treatment with rituximab significantly delays disease progression and the time until chemotherapy or radiotherapy compared with a watchful waiting approach.[69] However, an overall survival advantage has not been demonstrated with this approach.

As described above, patients with follicular lymphoma who are followed without therapy sometimes have spontaneous regressions that can be complete while the disease in other patients can convert to a more aggressive histology. Current guidelines suggest that "watch and wait" is an acceptable initial management approach for patients with low-grade follicular lymphoma who are asymptomatic; have no threatened end-organ function, cytopenias secondary to lymphoma, or bulky disease; and in whom the disease is not steadily progressing. If the watchful waiting approach is chosen, the patient should be evaluated at least every 3 to 6 months for 5 years and then annually, so that intervention can occur before serious problems occur.[49]

Single-Agent Rituximab

The approval of rituximab is arguably the most important development in the treatment of NHL. Its initial approval in 1997 was based on an open-label multicenter study that enrolled 166 patients with relapsed or recurrent indolent lymphoma.[70] Rituximab, given IV at a dose of 375 mg/m^2 weekly for 4 weeks, resulted in an overall response of 48% (complete response: 6%, partial response: 42%). The median time to progression for responders was 13.2 months and the median duration of response was 11.6 months. Other studies of single-agent rituximab in patients with relapsed or refractory indolent NHL have reported overall response rates of 40% to 60% and complete response rates of 5% to 10%.[71]

Based on the activity of rituximab in relapsed or refractory patients, it is currently being used as first-line therapy, either alone or in combination with chemotherapy.[71] When given as a single agent to patients with previously untreated indolent NHL, the overall response rate is 60% to 70% and the complete response rate is 20% to 30%. It is interesting to note that many of these patients remain in molecular remission (ie, polymerase chain reaction—negative) at 12 months. Single-agent rituximab is listed as an acceptable option for first-line therapy of follicular lymphoma, particularly for patients who cannot tolerate more intensive chemotherapy regimens.[49]

In patients who respond to rituximab, either alone or combined with chemotherapy, maintenance therapy with single-agent rituximab is often given to prolong the duration of remission. Rituximab is FDA approved as single-agent maintenance therapy in patients achieving a complete or partial response following induction chemotherapy. The FDA approval was based on a randomized controlled trial in previously untreated patients with advanced-stage follicular lymphoma treated with maintenance rituximab after CVP chemotherapy.[72] After a median follow-up of 11.5 years in the E1496 study, patients with indolent lymphoma receiving maintenance rituximab had longer median progression-free survival than patients on observation (4.8 vs 1.3 years). However, no significant difference in 10-year overall survival between maintenance rituximab and the observation group was observed (67% vs 59%).[73] Maintenance rituximab is expensive and may be associated with serious adverse drug reactions, including an increased risk of grades 3 or 4 infections. The NCCN guideline lists maintenance therapy with rituximab (one dose every 8 weeks for up to 2 years) as an option following first-line therapy for patients initially presenting with a high tumor burden.[49]

Rituximab maintenance following second-line therapy has also been evaluated in patients with relapsed or refractory disease. Two randomized trials have demonstrated a progression-free survival advantage with rituximab maintenance over observation for patients treated with induction chemotherapy.[74,75] Patients who develop progressive disease during or within 6 months of first-line maintenance rituximab will likely experience little, if any, benefit from maintenance therapy in the second-line setting. The NCCN guideline recommends optional maintenance therapy with rituximab (one dose every 12 weeks for 2 years) for patients who are in remission after second-line therapy.[49]

Most of the adverse drug reactions of rituximab are infusion-related, particularly after the first intravenous infusion, and consist of fever, chills, respiratory symptoms, fatigue, headache, pruritus, and angioedema. Premedication with oral acetaminophen 650 mg and diphenhydramine 50 mg is usually given 30 minutes before rituximab infusion. Duration of infusions may take up to 5 hours. The package insert recommends a step-up infusion rate of rituximab to decrease the risk of infusion-related events. The FDA has approved rapid infusions of rituximab, but they are not recommended in patients with clinically significant cardiovascular disease and high circulating lymphocyte counts (>5,000 cells/mm^3 [5×10^9/L]). Reactivation of hepatitis B has been reported in patients receiving chemotherapy, either alone or combined with rituximab. Hepatitis B testing is recommended in patients who are considering rituximab therapy.[49]

In addition to the intravenous formulation of rituximab, a subcutaneous formulation of rituximab was approved. In this formulation, rituximab is combined with recombinant human hyaluronidase, which allows rituximab to be rapidly dispersed and absorbed after subcutaneous administration. Subcutaneous administration shortens the administration time to 5 to 7 minutes as compared to several hours for the intravenous infusion. FDA approval for the subcutaneous rituximab was based on multiple randomized clinical trials that demonstrated non-inferior rituximab blood concentrations and comparable efficacy and safety for the two formulations.[76,77] Premedication with acetaminophen and antihistamine is still required before each dose of subcutaneous rituximab, and subcutaneous administration should only be considered after patients receive at least one full dose of a rituximab product by intravenous infusion with no severe adverse drug reactions.

Chemoimmunotherapy

Patients with high tumor burden or with disease-related symptoms are typically treated with chemoimmunotherapy, with or without maintenance therapy with an anti-CD20 monoclonal antibody. The rationale for the use of rituximab in combination with conventional agents is based on the clinical activity of both agents/regimens, non–cross-resistant mechanisms of action, non-overlapping toxicities, and synergistic antitumor activity in vitro. In a meta-analysis of randomized controlled trials, patients with indolent lymphoma treated with rituximab and chemotherapy had a significantly higher overall response rate and reduced risk of treatment failure and death.[78] Currently, the most widely used front-line regimen is R-CHOP or bendamustine plus rituximab (BR). Table 155-8 shows the CHOP regimen that is widely used in the treatment of NHL, and the development of the CHOP regimen is described in more detail later in this chapter.

TABLE 155-8

CHOP Regimen

Drug	Dose	Route	Treatment Days
Cyclophosphamide	750 mg/m^2	IV	1
Doxorubicin[a]	50 mg/m^2	IV	1
Vincristine[b]	1.4 mg/m^2	IV	1
Prednisone	100 mg	Oral	1-5
One cycle is 21 days			

[a] Another name for doxorubicin is hydroxydaunorubicin.

[b] Vincristine dose is typically capped at 2 mg.

Bendamustine is an alkylating agent with structural similarities to both alkylating agents and purine analogs. The mechanism of action of bendamustine is different from other alkylating agents and it does not show cross-resistance to other alkylating agents. When used as a single agent, bendamustine shows antitumor activity in relapsed or refractory indolent lymphomas. Overall and complete response rates of 70% to 80% and 30% to 35% have been reported, respectively, in phase II trials.[79] Two randomized, noninferiority studies have reported that BR is noninferior to R-CHOP for indolent lymphomas. In a randomized noninferiority phase III study of patients with advanced indolent lymphoma (with slightly over half follicular lymphoma patients), patients randomized to receive BR had longer median progression-free survival as compared to those in the R-CHOP group. In the subgroup analysis of patients with follicular lymphoma subtype, a significant benefit for progression-free survival was observed with BR versus R-CHOP.[80] In another study, BR was demonstrated to be noninferior to standard therapies (R-CHOP or R-CVP) for overall and complete response rate, with significant improvement in 5-year progression-free survival (65.5% vs 55.8%).[81,82] Both studies also reported that BR was associated with fewer infectious episodes and fewer hematological toxicities such as grade 3 to 4 leukopenia and neutropenia. BR was also associated with less peripheral neuropathy and alopecia.[80,81] However, dermatological toxicities, drug-related hypersensitivities, and vomiting were more common with BR. Based on these results, BR, R-CHOP, and R-CVP are all listed as first-line therapy of follicular lymphoma (category 1).[49]

Obinutuzumab-based chemoimmunotherapy regimens are also approved in the treatment of follicular lymphomas. Obinutuzumab is a humanized anti-CD20 monoclonal antibody developed to have lower complement-dependent cytotoxicity, but greater antibody-dependent cellular cytotoxicity, phagocytosis, and direct B-cell killing than rituximab. Obinutuzumab has been evaluated in both first- and second-line settings. In the first-line trial, patients with previously untreated advanced-stage follicular lymphoma were randomized to receive chemotherapy (CHOP, CVP, or bendamustine) combined with either obinutuzumab or rituximab.[83,84] Patients who achieved a complete or partial remission received maintenance therapy with the same antibody. Although progression-free survival at 3 years favored patients receiving obinutuzumab, overall survival was similar in the two groups. Serious adverse drug reactions such as infusion-related events occurred more frequently in patients receiving obinutuzumab. In the second-line setting, patients with indolent lymphoma (majority being follicular lymphoma) refractory to rituximab were randomized to bendamustine, either alone or combined with obinutuzumab for 6 cycles, followed by maintenance obinutuzumab therapy for 2 years.[85,86] Patients in the obinutuzumab arm had increased progression-free and overall survival as compared to bendamustine monotherapy. The NCCN guidelines list obinutuzumab, combined with chemotherapy, as first-line, second-line, and subsequent therapy options for treatment of follicular lymphoma.[49] To reduce the risk of infusion reactions associated with obinutuzumab, patients should receive premedication including glucocorticoids, acetaminophen, and antihistamines, as well as a step-up infusion rate. In addition, patients receiving obinutuzumab and bendamustine should receive prophylaxis for *Pneumocystis jiroveci* pneumonia and varicella zoster virus.

Lenalidomide

Lenalidomide is an immunomodulating agent that binds to the cereblon E3 ubiquitin ligase complex, which degrades transcription factors and leads to apoptosis of lymphoma cells.[87] The NCCN guidelines list rituximab-lenalidomide as a treatment option for first-line and second-line therapy for treatment of follicular lymphoma.[49] In the first-line setting, one phase III study compared rituximab and lenalidomide versus rituximab and chemotherapy (R-CHOP, BR, or R-CVP) in advanced-stage follicular lymphoma. Patients received different lenalidomide doses and treatment duration (maximum duration of 18 cycles) depending on their response. Maintenance rituximab was given to all patients. Complete response rates at 120 weeks and 3-year progression-free survival were similar in both arms. Safety profiles, however, differed between the two treatment arms, with more patients in the rituximab and chemotherapy group experiencing grade 3 or 4 neutropenia. Patients receiving lenalidomide and rituximab experienced more grade 3 or 4 cutaneous reactions.[88]

The combination of rituximab and lenalidomide was compared to lenalidomide monotherapy in patients with recurrent follicular lymphoma. Compared to lenalidomide monotherapy, the combination had higher overall and complete response rates. The time-to-progression was also longer in the rituximab and lenalidomide group (2.0 vs 1.1 year). Commonly reported toxicities of lenalidomide include neutropenia, fatigue, and thrombosis.[89]

Radioimmunotherapy

^{90}Y-Ibritumomab tiuxetan (Zevalin®) is an anti-CD20 radioimmunoconjugate used for patients with indolent NHLs.[90] It is a mouse antibody linked to yttrium-90$^{(90Y)}$, a radioisotope. Indolent lymphomas are known to be responsive to radiation therapy (ie, radiosensitive), and the rationale for radioimmunotherapy is that the antibody acts as a guided missile to deliver its payload (ie, radiation) to its target (ie, lymphoma cells that express the CD20 antigen). The specificity of the monoclonal antibody allows delivery of the radiation selectively to the tumor (and adjacent normal tissues).

^{90}Y-Ibritumomab tiuxetan has shown activity in relapsed and refractory patients with indolent or transformed lymphomas.[90] In patients who respond to radioimmunotherapy, the duration of remission can be more than several years. Radioimmunotherapy is generally well-tolerated. The major acute toxicities with both radioimmunoconjugates are infusion-related reactions and myelosuppression. The primary concern with radioimmunotherapy is the development of treatment-related myelodysplastic syndrome or acute myelogenous leukemia.

The decision to use radioimmunotherapy must be made carefully because of the complexity, risks, and costs of the treatment regimen. Because of safety concerns related to delivery of radiation to bone marrow, candidates for radioimmunotherapy usually have limited bone marrow involvement and adequate absolute neutrophil and platelet counts. Although medical oncologists usually select patients for therapy, the radioimmunotherapy regimen must be administered at a radiation oncology or nuclear medicine facility.

Phosphatidylinositol-3-Kinase (PI3K) Inhibitor

The B-cell receptor signaling pathway plays an important role in the maintenance and progression of FL. The PI3K pathway is downstream from the B-cell receptor and is essential for the survival of FL. Inhibition of PI3K reduces phosphatidylinositol 3,4,5-triphosphate (PIP_3), which is a messenger that affects pivotal cell function including cell proliferation, survival, and metabolism. Among the four isoforms of PI3K, PI3Kδ mediates B-cell receptor signaling and microenvironment support signals that promote the growth and survival of malignant B lymphocytes. Four PI3K inhibitors (idelalisib, copanlisib, duvelisib, and umbralisib) are currently approved for treatment of relapsed and refractory follicular lymphoma. Idelalisib is an isoform-selective PI3K inhibitor and targets specifically PI3Kδ, whereas copalisinb is a pan-class I PI3K inhibitor, predominantly targeting PI3Kα and PI3Kδ. Duvelisib targets PIK3Kδ and PI3Kγ, and umbralisib inhibits PI3Kδ and casein kinase-1ε (CK1ε). CK1ε is a component of the Wnt signaling pathway which has been shown to drive the pathogenesis of B-cell lymphoproliferative disorders.

The use of PI3K inhibitors for follicular lymphoma is based on three Phase II studies. In one study, patients with relapsed or refractory indolent NHL received oral idelalisib 150 mg twice daily until disease progression. The overall response rate was 57% in patients with follicular lymphoma who had relapsed within 24 months of chemoimmunotherapy, with a median duration of response of 11.8 months.[91,92] Similar results were reported with other PI3K inhibitors.[93–95] All of the PI3K inhibitors can cause severe neutropenia, diarrhea, infection, and pneumonia. Idelalisib is also associated with severe hepatotoxicity, severe diarrhea, colitis, and lung infection. Hypertension and hyperglycemia are more prominent with copanlisib because of its potent inhibition of PI3Kα. Severe skin infections have also been observed with copanlisib while duvelisib is associated with serious adverse drug reactions including infection and death. Umbralisib is associated with neutropenia, diarrhea, and transaminitis. The NCCN guidelines list idealisib, copanlisib, and duvelisib as treatment options for second-line therapy and umbralisib is listed as third-line therapy for patients with relapsed or refractory follicular lymphoma.[49]

Tazemetostat

Among patients with follicular lymphoma, 20% to 25% harbor an activating mutation of the epigenetic regulator EZH2. Such mutation allows the escape from the normal B-cell clonal selection process and allows GCB cells to survive and proliferate. Tazemetostat is a first-generation EZH2 inhibitor and is currently approved for EZH2 mutation positive in relapsed or refractory disease after two prior therapies, or EZH2 wild-type or unknown relapsed/refractory disease in patients who have no satisfactory alternative treatment options. In a trial of tazemetostat, patients with relapsed or refractory FL harboring an EZH2 mutation had a 71% overall response rate whereas patients without this mutation had an overall response rate of 33%.[96]

Axicabtagene Ciloleuce

Chimeric antigen receptor (CAR) T-cell therapies have also been explored in relapsed/refractory follicular lymphomas. In a phase 2 trial (ZUMA-5), 84 patients with relapsed/refractory follicular lymphoma after two or more lines of therapy received axicabtagene ciloleuce. The overall response rate was 94%, with 80% having a complete response. The 12-month progression-free and overall survival were 74% and 93%, respectively. However, grade 3 or above adverse drug reactions occurred in 85% of the patients, with cytokine release syndrome and neurologic toxicities occurring in 6% and 15%, respectively.[97]

Hematopoietic Stem Cell Transplantation

High-dose chemotherapy, followed by autologous or allogeneic HSCT, is another option for patients with relapsed follicular lymphoma.[98] In patients who are transplanted at the time of initial treatment failure, 5-year event-free survival is about 40% to 50%. Although the rate of recurrence is lower after allogeneic HSCT as compared with autologous HSCT, that benefit is offset by increased treatment-related mortality after allogeneic HSCT. The presence of a survival plateau after allogeneic HSCT suggests that some patients may be cured of their disease.

A recent study has evaluated the role of HSCT in relapsed/refractory follicular lymphoma following disease relapse after prior rituximab-based therapy. Allogeneic HSCT was associated with an increased risk of death on analysis. Autologous HSCT, on the other hand, was associated with a 3-year overall survival rate of 87%.[99] The current NCCN guideline lists autologous HSCT as an appropriate consolidative therapy for patients achieving second or third remission.[49] However, emerging data suggest that patients transplanted after their first or second relapse could achieve better outcomes than those who receive transplants later in their course of illness.[100]

Diffuse Large B-Cell Lymphoma

The DLBCLs are the most common lymphoma in the International NHL Classification Project, accounting for about 30% of all NHLs.[63] DLBCLs are characterized by the presence of large cells, which are similar in size to or larger than tissue macrophages and usually more than twice the size of normal lymphocytes. The median age at the time of diagnosis is in the seventh decade, but DLBCL can affect individuals of all ages, from children to older adults. Patients often present with a rapidly enlarging symptomatic mass, with B symptoms in about 30% to 40% of cases.[49] About 30% to 40% of patients with DLBCL present with extranodal disease; common sites include the head and neck, gastrointestinal tract, skin, bone, testis, and CNS. DLBCL is the most common type of diffuse aggressive lymphomas, which are characterized by an aggressive clinical behavior that leads to death within weeks to months if the tumor is not treated. Diffuse aggressive lymphomas are also sensitive to many chemotherapeutic agents, and some patients treated with chemotherapy can be cured of their disease.

Several factors correlate with response to chemotherapy and survival in patients with aggressive lymphoma. Because the IPI was originally developed based on patients with aggressive lymphoma, the IPI score correlates with prognosis (see Table 155-7).[52] As described above, the revised NCCN-IPI score may more accurately predict prognosis in patients receiving rituximab-containing combination chemotherapy.[53]

Therapy of DLBCL is based on the Ann Arbor stage, IPI (or revised IPI) score, and other prognostic factors.[49] About one-half of patients present with localized (stage I or II) disease. However, many patients present with large bulky masses (ie, larger than 10 cm), and patients with bulky stage II disease are treated with the same approach used for patients with advanced disease (stage III or IV).

Treatment of Localized Disease (Stages I and II)

⑪ Before 1980, radiation therapy was the primary treatment for patients with localized DLBCL. Five-year disease-free survival with radiation therapy alone was about 50% and 20% in patients with stage I and stage II disease, respectively.[49] Randomized trials in the 1980s showed that radiation therapy followed by chemotherapy resulted in significantly longer disease-free and overall survival as compared with radiation therapy alone. Other studies reported excellent results with a short course of chemotherapy (three cycles) followed by involved-field radiotherapy or six to eight cycles of CHOP chemotherapy, with or without consolidation radiotherapy. With either of these approaches, 5-year progression-free survival was more than 90% for patients with stage I disease and about 70% for patients with stage II disease.[49]

Because the most effective approach was not clear, the SWOG performed a randomized trial that compared three cycles of CHOP and involved-field radiotherapy or six cycles of CHOP in patients with stage I and nonbulky stage II aggressive lymphoma.[101] Patients treated with three cycles of CHOP plus radiotherapy had significantly better 5-year progression-free and overall survival with a lower incidence of life-threatening toxicity than patients treated with CHOP alone. However, with longer follow-up, the differences in progression-free or overall survival were no longer significant between the two arms.

In the rituximab era, most patients with localized disease are treated with either three to four cycles of R-CHOP followed by radiotherapy or six to eight cycles of R-CHOP with no radiotherapy. Although these two treatment options have not been directly compared in a randomized controlled trial, observational data show similar 5-year overall survival in patients with stage I and II DLBCL. Patients who received the abbreviated course of R-CHOP plus radiotherapy experienced less acute toxicity and a lower risk of requiring second-line therapy.[102] Based on these findings, three cycles of R-CHOP followed by locoregional radiation is recommended for patients with localized, nonbulky DLBCL. Alternatively, if the disease presents at sites where radiotherapy may lead to significant morbidity, six cycles of R-CHOP without radiation can be considered.[49]

A recent study has examined the use of interim PET scans to determine the need for radiotherapy. Patients with a negative interim PET scan received four cycles of R-CHOP alone with no radiotherapy while those with a positive PET scan were subsequently treated with radiotherapy and ibritumomab tiuxetan. Patients with both positive and negative interim PET scans demonstrated similarly excellent survival outcomes, suggesting the potential role of interim PET scans to guide treatment of localized DLBCL.[102]

Treatment of Advanced Disease (Bulky Stage II, Stages III, and IV)

It has been known since the late 1970s that intensive combination chemotherapy can cure some patients with disseminated DLBCL.[46] Initial studies with cyclophosphamide, vincristine (Oncovin®), and prednisone or prednisolone (COP; same as CVP) produced a plateau on the survival curve of just 10%, with a median survival of less than 1 year. Based on the activity of single-agent doxorubicin, McKelvey et al. developed the CHOP regimen (see Table 155-8).[103] A few years later, a SWOG study showed that CHOP was more active than COP, and CHOP chemotherapy rapidly became the treatment of choice for patients with aggressive lymphomas.[104] Studies in larger numbers of patients showed that about 50% of patients had a complete remission to CHOP chemotherapy, and 50% to 75% of the patients who had a complete response (about one-third of all patients) experienced long-term disease-free survival and cure of their disease.

To improve these results, many investigators used several approaches to develop second- and third-generation regimens in the 1980s. Results of phase II trials suggested that these second- and third-generation regimens were more active than CHOP, with slightly higher complete response rates and improved disease-free survival rates. However, they were also more difficult to administer, more toxic, and more expensive. Based on these results, many oncologists adopted one of these second- or third-generation combination regimens as their standard regimen for patients with advanced aggressive lymphomas.

Many randomized studies have compared different combination regimens in patients with aggressive lymphoma. Although the results of these studies show that no one regimen is superior to another, they demonstrate the superiority of anthracycline-containing regimens over those that do not contain an anthracycline. In the largest and most widely cited study, the SWOG initiated a randomized trial in 1986 that compared CHOP to three of the most commonly used third-generation regimens in patients with advanced NHL. At the time of the initial publication (median follow-up: 35 months), no differences in disease-free and overall survival were observed between the four groups.[105] Furthermore, no significant differences in disease-free or overall survival were observed in any subgroup of patients. But the risk of treatment-related mortality was higher in patients receiving one of the third-generation regimens. Extended follow-up of that trial shows that about 35% of patients who participated in that trial are probably cured of their disease, regardless of the initial combination chemotherapy regimen. Interestingly, the overall survival is about 10% higher than the disease-free survival, which probably reflects the effectiveness of salvage high-dose chemotherapy with autologous HSCT (see the "Treatment of Refractory or Relapsed Disease" section).

Based on the lack of survival benefit with the newer combination chemotherapy regimens, the less-complicated and less-expensive CHOP regimen was considered as the treatment of choice for most patients with DLBCL and other aggressive NHLs for many years. Even with CHOP chemotherapy, however, less than 50% of patients with DLBCL were cured of their disease and most patients who relapse after an initial response do so in the first 2 years. New treatment approaches were needed.

Based on the encouraging results of R-CHOP in indolent lymphomas, several studies evaluated this combination in aggressive lymphomas. The first randomized controlled trial that established the efficacy of R-CHOP in advanced-stage DLBCL showed that R-CHOP significantly increased complete response rates and overall survival in older adults (≥60 years old) as compared with CHOP alone (discussed in the "Treatment of Older Patients with Advanced Disease" section).[106] Although the results of that study established R-CHOP as standard therapy in older patients, the role of R-CHOP in the treatment of younger patients was not clear. That issue was addressed in the MabThera International Trial, which enrolled younger (18-60 years old) patients with good-prognosis DLBCL.[107] Patients randomized to receive rituximab plus CHOP-like chemotherapy had significantly higher complete response rates (86% vs 68%) and longer 3-year event-free and overall survival (79% vs 59%; HR 0.44 and 93% vs 84%; HR 0.40, respectively). Updates from the study cohort indicate that the survival benefits of adding rituximab are sustained at 6 years with no increase in the incidence of secondary malignancies.[108] Based on these trial results, rituximab received FDA approval for first-line treatment in combination with CHOP or CHOP-like chemotherapy and R-CHOP is recommended for all patients with advanced-stage DLBCL in the current NCCN guideline.[49]

Several studies attempted to improve treatment results by increasing chemotherapy dose (ie, dose-intensity), shortening the interval between chemotherapy cycles (ie, dose-density), or both. Because of the increased risk of severe neutropenia, these treatment approaches require growth factor support. Dose-dense chemotherapy, where the interval between cycles is shortened from 3 to 2 weeks, has been evaluated in randomized trials. Before the rituximab era, event-free, and overall survival rates were longer with biweekly CHOP-14 compared to standard CHOP-21 every 21 days.[109]

However, long-term follow-up data show that with the addition of rituximab, the survival benefit associated with a dose-dense schedule is not superior to that of R-CHOP-21.[110,111] In one of the trials conducted in older adults, the incidence of severe neutropenia was significantly higher despite an increased use of granulocyte colony-stimulating factor.[111]

Treatment outcomes for high-risk patients according to the IPI (or revised IPI) score are unsatisfactory. High-risk groups generally include all patients older than 60 years and those with an IPI score of 3 or more (or an age-adjusted IPI score of ≥2). Since progression-free survival is only about 50% in these high-risk patients treated with R-CHOP, other more aggressive treatments, preferably as part of a clinical trial, should be considered in these patients.

One approach is to give high-dose chemotherapy with autologous HSCT as intensive consolidation in high-risk patients with DLBCL who achieve a remission with standard chemotherapy. This approach improves progression-free survival in patients with high-risk disease (age-adjusted IPI score of ≥2) who have a response to CHOP-based chemotherapy.[49]

In summary, all patients with bulky stage II, stage III, or stage IV disease should be treated with R-CHOP or rituximab and CHOP-like chemotherapy until a complete response is achieved (usually four to six cycles).[49] The use of long-term maintenance therapy following a complete response has not been shown to improve overall survival. Treatment outcomes for high-risk patients according to the IPI (or revised IPI) score are unsatisfactory and alternative treatment approaches, preferably as part of a clinical trial, should be considered in these patients. High-dose chemotherapy with autologous HSCT should be considered in high-risk patients who respond to standard chemotherapy and are candidates for autologous HSCT.[49]

Treatment of Older Patients with Advanced Disease

More than one-half of patients with NHL are older than 60 years of age at diagnosis, and about one-third are older than age 70 years. The International Non-Hodgkin Lymphoma Prognostic Factors Project showed that patients older than 60 years had a significantly lower complete response rate and overall survival.[52] The reasons for the poorer outcome in older adults are not clear. Older patients do not tolerate intensive chemotherapy as well as younger patients, and some studies report that older patients have a higher risk of treatment-related mortality. As a result, many clinicians treat older adults with reduced dose or less-aggressive chemotherapy regimens. In general, these less-intensive regimens use anthracyclines with less cardiotoxicity than doxorubicin, substitute mitoxantrone for doxorubicin, or use short-duration weekly therapy.[112]

Over the past few years, several nonrandomized and randomized trials have evaluated different treatment approaches in older patients with aggressive NHL. The results of these studies suggest that carefully selected older adults with good performance status and without significant comorbidities can tolerate aggressive anthracycline-containing regimens as well as younger patients. These patients should be treated initially with full-dose R-CHOP or similar regimens; dosages can be reduced later if severe toxicity occurs. Hematopoietic growth factors may allow older adults to maintain dose intensity.[112]

The combination therapy, R-CHOP, has replaced CHOP as standard treatment for older adults with aggressive lymphoma, based on the results of the Groupe d'Etude des Lymphomes de l'Adulte (GELA) study.[106] In that study of older adults with DLBCL, patients who were randomized to receive R-CHOP had a significantly higher complete response rate and longer event-free and overall survival as compared with those who received CHOP. After 10 years of follow-up, progression-free survival was significantly longer among those who received R-CHOP than CHOP.[106] A higher risk of death or secondary cancer was not observed with the addition of rituximab to CHOP after 10 years of follow-up. In another randomized controlled trial conducted primarily in the United States (Eastern Cooperative Oncology Group 4494), older adults (≥60 years old) who received rituximab, either as induction or maintenance with CHOP chemotherapy, had significantly longer failure-free survival as compared with those not given rituximab during their treatment course.[113] Maintenance therapy with single-agent rituximab did not provide any additional benefit in patients who received R-CHOP as induction therapy. Rituximab is given differently in the two studies. In the GELA study, rituximab is given on day 1 (the same day that cyclophosphamide, doxorubicin, and vincristine are administered) with each cycle of CHOP chemotherapy.[106] In the Eastern Cooperative Oncology Group 4494 study, R-CHOP was modeled after the regimen developed by Czuczman et al.: two doses of rituximab are given before cycle 1, and one dose is given before cycles 3, 5, and 7 (if administered).[114] In most NHL protocols and in clinical practice, rituximab is given on day 1 of each cycle of CHOP chemotherapy.

Previous trials have evaluated different drugs, including rituximab, as maintenance treatment in DLBCL but have failed to show survival benefits.

Lenalidomide as maintenance in older adults (60-80 years old) who had responded to R-CHOP was recently evaluated in the REMARC trial. Maintenance lenalidomide for 24 months prolonged progression-free survival but did not improve overall survival and was associated with a higher premature discontinuation rate.[115] Based on these results, lenalidomide is an option if maintenance therapy is considered in older adults who have responded to treatment.[49]

Treatment of Refractory or Relapsed Disease

⑫ Although many patients with aggressive NHL experience long-term survival and cure with intensive chemotherapy, about 10% to 20% of patients fail to achieve a complete remission and about 20% to 30% of patients who do achieve a complete remission will subsequently relapse. Therefore, about 30% to 40% of all patients with aggressive NHL will require salvage therapy at some point during their disease course. Response to salvage therapy depends on the initial responsiveness of the tumor to chemotherapy. Patients who achieve an initial complete remission and then relapse generally have a better response to salvage therapy than those who are primarily or partially resistant to chemotherapy.[116]

Many conventional-dose salvage chemotherapy regimens have been used in patients with relapsed or refractory NHL. Many patients who respond to salvage therapy (ie, chemosensitive relapse) will then receive high-dose chemotherapy with autologous HSCT. To avoid cross-resistance, most salvage regimens incorporate drugs not used in the initial therapy. Some of the more commonly used salvage regimens include ICE, dexamethasone, cytarabine, cisplatin (DHAP), etoposide, methylprednisolone, cytarabine, cisplatin (ESHAP), mesna, ifosfamide, mitoxantrone, etoposide (MINE), gemcitabine, dexamethasone, cisplatin (GDP) and no one regimen is superior to any other regimen.[117] With these salvage regimens, about 30% to 50% of patients achieve a complete response, with a median duration of remission of 1 to 2 years. Only about 5% to 10% of patients will have long-term disease-free survival.[116]

Rituximab is sometimes added to these salvage regimens. It is recommended, however, to exclude rituximab in second-line therapy if the patient's disease is refractory or if the duration of remission is less than 6 months. One study (CORAL study) compared two salvage regimens (R-ICE and R-DHAP) in patients with relapsed or refractory DLBCL, followed by autologous HSCT.[118] No significant difference in 3-year event-free survival or overall survival was observed between R-ICE and R-DHAP. However, patients who had received prior rituximab and experienced early relapse (defined as less than 12 months after diagnosis) had a poor prognosis. New treatment strategies are needed to improve the response rates of salvage regimens.

To improve the cure rate, many studies have evaluated high-dose chemotherapy with autologous HSCT as intensive consolidation therapy in patients who respond to salvage therapy. In the PARMA study, patients with relapsed aggressive NHL who had a response to DHAP salvage therapy were randomized to receive either high-dose chemotherapy or continued DHAP therapy.[119] Patients who received high-dose chemotherapy had significantly longer 5-year disease-free survival (46% vs 12%) and overall survival (53% vs 32%) than those treated with conventional salvage therapy. Further analysis of that study showed that patients who relapsed within 12 months of their initial diagnosis were less likely to benefit from high-dose chemotherapy than patients who relapsed after 12 months. Based on a review of the available evidence, including the PARMA study, high-dose chemotherapy with autologous HSCT is considered to be the treatment of choice in younger patients with chemotherapy-sensitive relapse.[49] High-dose chemotherapy with autologous HSCT is not recommended in patients with untested or chemotherapy-refractory relapse.

In patients who have failed multiple lines of treatment, several agents have been studied, including selinexor and chimeric antigen receptor (CAR) T-cell therapy. CAR T-cell therapy is a type of adoptive immunotherapy where the patient's own T-lymphocytes are collected, modified genetically in the laboratory to target antigens on malignant cells, and then administered back to the patient by infusion.[120] In recent years, three CAR T-cell therapies, tisagenlecleucel, axicabtagene ciloleucel, and lisocabtagene maraleucel have been approved by the FDA for relapsed and refractory DLBCL after two or more lines of systemic treatment have failed. The approval of CAR T-cell therapies was based on high response rates reported in phase II trials, which compared favorably to historical data. In the JULIET trial, an overall best response rate of 52% was reported in 93 patients with refractory disease treated with tisagenlecleucel.[121] In the ZUMA-1 trial, a response rate of 82% and 18-month overall survival of 52% was reported in 101 patients with refractory disease.[122] The TRANSCEND trial, with 256 evaluable patients, reported an objective response rate of 73% among those with refractory disease who received lisocabtagene maraleucel.[123] Ongoing randomized trials are investigating the role of CAR T-cell therapy as first-line therapy or in combination with other immunotherapy agents in relapsed and refractory DLBCL[124,125]

CAR T-cell therapies are associated with a high incidence of cytokine release syndrome, which is characterized by fever, hypoxia, and hypotension, and may require the use of vasopressors in severe cases. Severe neurological toxicities such as encephalopathy and seizures can also occur, usually within days of T-cell infusion. While mild episodes can be symptomatically managed, moderate-to-severe grades of cytokine release syndrome and neurological toxicities may require immunosuppressants including tocilizumab and corticosteroids.[49,120,126]

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) is found in 6% of cases in the International Lymphoma Classification Project.[63] The chromosomal translocation t(11;14) occurs in most cases of MCL. MCL usually occurs in older adults, particularly in men, and most patients have advanced disease at the time of diagnosis (see Table 155-6). Extranodal involvement is found in about 90% of cases. The course of the disease is moderately aggressive; the median overall survival is about 3 years, with no evidence of a survival plateau.

Both aggressive and less-aggressive chemotherapy regimens have been evaluated in patients with disseminated MCL. One widely used aggressive combination regimen is cyclophosphamide, vincristine, doxorubicin, dexamethasone alternating with methotrexate and cytarabine (hyperCVAD) with or without rituximab. Overall response rates to these regimens are about 90%, with long-term progression-free survival rates of 59% and 35% at 5 and 10 years, respectively.[127] Less-aggressive regimens are often used for patients who are not candidates of HSCT. Because MCL usually expresses CD20, rituximab, either alone or combined with CHOP and bendamustine, has been used with some success in patients with newly diagnosed and relapsed MCL.[80,128] In a phase III study, BR was compared to R-CHOP for first-line therapy in patients with advanced follicular, indolent, and MCL. In the MCL subgroup, progression-free survival was higher with BR compared to R-CHOP up to 5 years after treatment completion, and it is associated with less hematologic toxicities.[80–82] However, a higher number of secondary malignancies were observed in the BR group during long-term follow-up.[82] Another less-aggressive option that has been found to yield favorable results was lenalidomide in combination with rituximab, with 5-year progression-free and overall survival rates of 63.9% and 77.4%, respectively.[129] Bortezomib (Velcade®), in combination with rituximab, cyclophosphamide, doxorubicin, and prednisolone, (VR-CAP, similar to R-CHOP regimen but with bortezomib replacing vincristine) is also indicated for newly diagnosed MCL.[130] In a phase III randomized study, patients with newly diagnosed MCL who were ineligible or not considered for HSCT received R-CHOP or VR-CAP. After a median follow-up of 40 months, median progression-free survival was longer in the VR-CAP arm compared to R-CHOP (24.7 vs 14.4 months). Rates of neutropenia and thrombocytopenia were higher in the VR-CAP group.[130]

Despite the high response rates, MCL is not considered curable with standard chemotherapy. Therefore, younger patients who have an initial response to chemotherapy often undergo autologous or allogeneic HSCT as consolidation therapy. The NCCN guidelines recommend that patients with advanced-stage MCL be treated initially with rituximab and combination chemotherapy, followed by autologous HSCT as first-line consolidation therapy.[49] In patients who respond to autologous HSCT, maintenance rituximab or lenalidomide are options that have been demonstrated to prolong progression-free and overall survival.[131–133] Findings from a prospective study suggest that similar survival benefits are also associated with the use of maintenance rituximab after R-CHOP in older patients who are not candidates for autologous HSCT.[134]

Unfortunately, most patients with MCL eventually relapse and are treated with salvage therapy or enrolled in trials of investigational agents, some of which are directed at molecular targets. First-line regimens such as R-CHOP, VR-CAP, and bendamustine can be considered if they have not been previously given.[49] Bortezomib with or without rituximab is also approved for the treatment of MCL that has relapsed after at least one prior therapy.

Novel agents that have been approved for the treatment of relapsed or refractory MCL include the Bruton tyrosine kinase (BTK) inhibitors ibrutinib, acalabrutinib, and zanubrutinib. In a phase III randomized trial, ibrutinib had a higher response rate and longer median duration of response with a more favorable safety profile than temsirolimus.[135] Addition of rituximab to ibrutinib was further evaluated in a phase II trial that reported a response rate of 88%, with a median duration of response of 46 months.[136] Other oral BTK inhibitors, acalabrutinib and zanubrutinib, have demonstrated overall response rates of more than 80% in phase II trials in patients with relapsed and refractory MCL.[137] The most common adverse drug reactions of BTRK inhibitors include diarrhea and fatigue. Since cytopenias are also common, complete blood counts should be monitored monthly while patients are on treatment. Bleeding may rarely occur during the first 6 months of BTK inhibitor therapy. Cases of new-onset atrial fibrillation have also been reported. A CAR T-cell therapy, brexucabtagene autoleucel, has also recently been approved for the treatment of relapsed and refractory mantle cell lymphoma in adult patients. Approval was granted based on ZUMA-2, a single-arm trial that demonstrated a response rate of 93% and a 12-month overall survival rate of 83%.[138]

EVALUATION OF THERAPEUTIC OUTCOMES

Hodgkin lymphoma and NHLs tend to respond well to radiation, chemotherapy, and biologic therapy. The goal of therapy for patients with Hodgkin lymphoma and aggressive NHL is long-term survival and cure. The therapeutic goal in patients with indolent NHLs is less clear because of the indolent nature of the disease and the lack of convincing evidence showing that therapy prolongs survival. Therapeutic responses should be evaluated based on physical examination, radiologic evidence, PET/CT scanning, and other positive findings at baseline. The current standard of care to evaluate response to treatment in Hodgkin lymphoma, follicular lymphoma, and DLBCL is PET imaging. As described earlier, the 5-point scale is recommended for PET-CT interpretation where a Deauville score of 1, 2, or 3 (uptake less than or equivalent to liver) indicates complete response, even in the presence of a persistent mass. If salvage treatment is considered based on a metabolically active residual mass, a biopsy or follow-up scan should be considered.[50] CT is advised for other lymphomas with low or variable FDG avidity. The rapidity of response to therapy in patients with indolent NHL depends on the choice of therapy. Early interim PET-CT scans may also possess prognostic value in patients with advanced Hodgkin lymphoma.[18] In NHL, the prognostic value of interim PET-CT scans is less established and is currently not recommended to guide changes in therapy.[49] Patients should be clinically monitored every 3 months for 2 years, then every 6 to 12 months as appropriate. Surveillance scans after disease remission has been achieved are currently not advised, especially in Hodgkin lymphoma and DLBCL, but they can be considered in the event of equivocal findings at the end of treatment or in indolent lymphomas with residual disease.[50]

CONCLUSION

Hodgkin lymphoma and NHL are the two primary histologic classifications of lymphoma. Hodgkin lymphoma is defined by the presence of Reed–Sternberg cells. Restaging PET-CT serves to guide patient-specific treatment plans primarily comprised of combination chemotherapy with or without radiation therapy. The primary combination chemotherapy utilized is ABVD. NHL is a much more heterogeneous group of malignancies and is classified by a combination of morphology, immunophenotype, genetic features, and clinical features. Treatment response is often based on the aggressiveness of the NHL. Aggressive NHLs, such as DLBCL, can often be cured with combination chemoimmunotherapy with R-CHOP. Indolent NHLs, such as follicular lymphoma, are often uncurable but can be managed long-term with a variety of different treatment approaches. In the relapsed setting, salvage chemoimmunotherapy is used along with high-dose chemotherapy followed by autologous HSCT. Several novel agents, including the chimeric antigen receptor T-cell therapy is a new approach for NHL and an area of ongoing research.

ABBREVIATIONS

ABC	activated B-cell–like
ABV	doxorubicin (Adriamycin®), bleomycin, vinblastine
ABVD	doxorubicin (Adriamycin®), bleomycin, vinblastine, and dacarbazine
ADC	antibody-drug conjugate
AIDS	acquired immune deficiency syndrome
BEACOPP	bleomycin, etoposide, doxorubicin (Adriamycin®), cyclophosphamide, vincristine (Oncovin®), procarbazine, and prednisone
BR	bendamustine and rituximab
BTK	Bruton tyrosine kinase
CHOP	cyclophosphamide, doxorubicin, vincristine (Oncovin®), prednisone
COP	cyclophosphamide, vincristine (Oncovin®), and prednisone or prednisolone

COPP	cyclophosphamide, vincristine, procarbazine, and prednisone
CT	computed tomography
CVP	cyclophosphamide, vincristine, and prednisone
DHAP	dexamethasone, cytarabine, cisplatin
DLBCL	diffuse large B-cell lymphoma
EBV	Epstein-Barr virus
EPOCH	etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin
ESHAP	etoposide, methylprednisolone, cytarabine, cisplatin
ESR	erythrocyte sedimentation rate
FDA	Food and Drug Administration
FLIPI	Follicular Lymphoma International Prognostic Index
GCB	germinal center B-cell like
GDP	gemcitabine, dexamethasone, cisplatin
GELA	Groupe d'Etude des Lymphomes de l'Adulte
GHSG	German Hodgkin Study Group
GVD	gemcitabine, vinorelbine, and pegylated liposomal doxorubicin
HAART	highly active antiretroviral therapy
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HR	hazard ratio
HSCT	hematopoietic stem cell transplantation
Hyper CVAD	cyclophosphamide, vincristine, doxorubicin, dexamethasone alternating with methotrexate and cytarabine
ICE	ifosfamide, carboplatin, and etoposide
IFRT	involved-field radiation
IPI	International Prognostic Index
IPS	International Prognostic Score

ISRT	involved-site radiation therapy
JAK–STAT	Janus kinase–signal transduction and transcription
KSHV	Kaposi sarcoma–associated herpesvirus
LDH	lactate dehydrogenase
MALT	mucosa-associated lymphoid tissue
MCL	mantle cell lymphoma
MINE	mesna, ifosfamide, mitoxantrone, etoposide
MMAE	monomethyl auristatin
MOPP	mechlorethamine, vincristine, procarbazine, and prednisone
MOPPEBVCAD	mechlorethamine, vincristine, procarbazine, prednisone, epidoxorubicin, bleomycin, vinblastine, lomustine, doxorubicin, and vindesine
NCCN	National Comprehensive Cancer Network
NHL	non-Hodgkin lymphoma
NLPHL	nodular lymphocyte-predominant Hodgkin lymphoma
PET	positron emission tomography
PI3K	phosphatidylinositol-3-kinase
PJP	Pneumocystis jiroveci pneumonia
R-CHOP	rituximab, cyclophosphamide, doxorubicin, vincristine (Oncovin®), prednisone
REAL	Revised European-American Classification of Lymphoid Neoplasms
RICE	rituximab, ifosfamide, carboplatin, and etoposide
SEER	surveillance, epidemiology, and end results
SWOG	Southwest Oncology Group
WHO	World Health Organization

SELF-ASSESSMENT QUESTIONS

1. What is the first-line treatment of choice for a patient with Stage IIA Classical Hodgkin lymphoma?

    A. ABVD chemotherapy +/− Involved field radiation

    B. Surgical resection

    C. Involved field radiation alone

    D. All of the above

2. Which of the following is *not* a “B” symptom?

    A. Night sweats

    B. Fever

    C. Pruritus

    D. Weight loss (>10%)

3. A 50-year-old white male presents with fatigue, weight loss, and fever and is later diagnosed with Stage IV Hodgkin lymphoma. Additional labs include: Hgb 9.1 g/dL (91 g/L; 5.65 mmol/L), WBC 23,000/μL (23×10^9/L), Plt 120,000/μL (120×10^9/L), albumin 3.2 g/dL (32 g/L), SCr 1.1 g/dL (97 μmol/L), and bili 1 mg/dL (17.1 μmol/L). What would be the most effective initial risk-adapted treatment for this patient?

   A. COPP/ABVD

   B. ABVD

   C. MOPP

   D. Escalated dose BEACOPP

4. A 22-year-old male with Stage IV Hodgkin lymphoma wants to retain fertility. What chemotherapy regimen would you recommend for this patient?

   A. ABVD

   B. MOPP

   C. ChlVPP

   D. MOPP/ABV hybrid

5. A 25-year-old female is diagnosed early-stage Hodgkin lymphoma with favorable prognosis. She is going to receive four cycles of ABVD. What is the overall survival rate for this patient?

   A. >10%

   B. >30%

   C. >60%

   D. >90%

6. Which of the following long-term toxicities is a greater concern for escalated dose BEACOPP as compared with ABVD?

   A. Cardiac disease

   B. Secondary malignancy

   C. Interstitial pulmonary fibrosis

   D. Renal insufficiency

7. Which of the following is true when one compares the A-AVD regimen versus the ABVD regimen?

   A. Replaces the bleomycin for brentuximab vedotin

   B. Should not be used in patients with baseline pulmonary fibrosis

   C. Replaces the bleomycin for actinomycin

   D. Has a lower risk of peripheral neuropathy

8. Brentuximab is a monoclonal antibody targeted against lymphoma cells. What is the molecular target of brentuximab?

   A. CD20

   B. CD30

   C. CD52

   D. LAP (lymphoma-associated protein)

9. Which of the following classification systems is currently used for non-Hodgkin lymphoma?

   A. REAL-WHO

   B. Luke-Collins

   C. Kiel

   D. International Working Formulation

10. What is the clinical objective of the IPI and FLIPI score?

    A. To classify the lymphoma as either indolent or aggressive

    B. To predict likelihood for conversion to a more aggressive histology

    C. To classify the lymphoma into molecular subtypes

    D. To predict prognosis (ie, survival)

11. What is the appropriate treatment for a newly diagnosed patient with advanced-stage follicular lymphoma?

    A. Obinutuzumab and bendamustine

    B. Rituximab and lenalidomide

    C. Rituximab and CHOP chemotherapy (R-CHOP)

    D. All of the above are appropriate treatment options, depending on patient and tumor characteristics and patient and physician preferences

12. Which of the following terms best describe Zevalin?

    A. Monoclonal antibody

    B. Radioimmunoconjugate

    C. Immunotherapy

    D. Recombinant protein

13. What is the appropriate treatment for a newly diagnosed patient with advanced-stage diffuse large B-cell lymphoma?

    A. Rituximab and CHOP chemotherapy (R-CHOP)

    B. Bendamustine

    C. CHOP chemotherapy

    D. Idelalisib

14. Which of the following statements best describe the results of appropriate treatment in patients with advanced-stage diffuse large B-cell lymphoma?

    A. About 30% to 60% of patients can be cured of their cancer

B. About 60% to 90% of patients can be cured of their cancer

C. Patients are not cured of their disease, but they will probably live longer

D. Patients will probably not live longer, but they may have improved quality of life

15. Which of the following chemotherapy regimens warrant primary prophylaxis with granulocyte colony-stimulating factor?

A. Dose-dense CHOP

B. Escalated-dose BEACOPP

C. BEACOPP-14

D. All of the above

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** ABVD chemotherapy +/− involved field radiation therapy remains the most well studied and clinically proven therapy in most patients with early-stage disease. Although other chemotherapy regimens may be an option, ABVD was the only answer that involved chemotherapy. Historically radiation therapy was primarily used for early-stage Hodgkin lymphoma, but chemotherapy has demonstrated fewer long-term complications.

2. **C.** By definition, B symptoms include unexplained fevers >38°C (100.4 °F), drenching night sweats, and/or weight loss of >10% body weight within 6 months of diagnosis. Pruritus and alcohol intolerance are findings that can occur with Hodgkin lymphoma but are not considered B symptoms.

3. **D.** The key to this question is the “risk adapted” portion. Escalated dose BEACOPP allows doses to be increased according to the patient’s tolerance and response. This can be used in a select group of patients with high IPS scores and age less than 60. This patient’s poor-risk features include albumin <4 g/dL (40 g/L), hemoglobin <10.5 g/dL (105 g/L; 6.52 mmol/L), male, stage IV disease, age >45 years, white blood cell count >15,000 cells/mm^3 (15 × 10^9/L), with an IPI score >4.

4. **A.** MOPP and MOPP-like regimens (which include ChlVPP and MOPP/ABVD hybrids) deliver large amounts of alkylating agents. Alkylating agents are known to cause decreased fertility. Of the regimens available to choose from in this question, ABVD offers the lowest exposure to alkylating agents.

5. **D.** Hodgkin lymphoma boasts one of the highest cure rates of all cancer diagnoses. Cure rates with initial and subsequent therapies in patients with early-stage Hodgkin lymphoma are in the 90% to 95% range. Cure rates in patients with stage III and IV disease are lower, but still in the 60% to 80% range.

6. **B.** As with Question 4 above, increasing exposure to alkylating agents increases both the risk of sterility and secondary malignancies. Additionally, topoisomerase II inhibitors are associated with secondary malignancies. The key medications in escalated dose BEACOPP that contribute to the risk of secondary malignancies include etoposide, doxorubicin, cyclophosphamide, and procarbazine.

7. **A.** The A-AVD regimen was designed to replace bleomycin with brentuximab vedotin. Bleomycin is known to cause pulmonary fibrosis and should be avoided in patients with known baseline pulmonary fibrosis. Brentuximab vedotin can cause peripheral neuropathy, and when combined with doxorubicin, vinblastine and dacarbazine, has a higher incidence of neuropathy versus ABVD.

8. **B.** Brentuximab targets CD30. Most classical Hodgkin lymphoma cells express or overexpress CD30 on their cell surface.

9. **A.** The REAL-WHO classification system is currently used for classifying the various subtypes of non-Hodgkin lymphomas. The system categorizes lymphoid malignancies into B-cell lymphomas and T-cell (and natural killer cell) lymphomas.

10. **D.** Both IPI and FLIPI assist clinicians to predict the prognosis of a patient with non-Hodgkin lymphoma. IPI is used for diffuse large B-cell lymphomas, while FLIPI is used for follicular lymphomas.

11. **D.** Many therapeutic options are available for a newly diagnosed patient with advanced-stage follicular lymphoma, and the choice of therapy

depends on patient and tumor characteristics, as well as patient and physician preferences. Refer “Treatment of Advanced Disease (Stages II Bulky, III, and IV)” section under Non-Hodgkin Lymphoma for more information.

12. **B.** Zevalin, or ^{90}Y-ibritumomab tiuxetan, is an anti-CD20 radioimmunoconjugate that is available for patients with indolent non-Hodgkin lymphomas.
13. **A.** R-CHOP is one of the first-line chemotherapies recommended by current NCCN guidelines for the treatment of newly diagnosed diffuse large B-cell lymphoma.
14. **B.** Based on the results of landmark RCHOP studies such as the MabThera International Trial (MiNT), RCHOP has improved the cure rate of diffuse large B-cell lymphoma among patients with advanced disease from about 60% to 90%. See the “Diffuse Large B-Cell Lymphoma” section and its subsection “Treatment of Advanced Disease” for more details.
15. **D.** Granulocyte colony-stimulating factor should be given for primary prophylaxis in chemotherapy regimens that have a risk of febrile neutropenia of more than 20%. This includes dose-dense RCHOP, escalated-dose BEACOPP, and BEACOPP-14.

Chapter 156: Ovarian Cancer

Grace A. Martin; Judith A. Smith

KEY CONCEPTS

KEY CONCEPTS

① Ovarian cancer is denoted “the silent killer” because of the nonspecific signs and symptoms that contribute to the delay in diagnosis. The few patients who present with disease still confined to the ovary will have a 5-year survival rate greater than 90%, but most patients present with advanced disease and have a 5-year survival rate around 30%.

② Ovarian cancer is a sporadic disease with less than 20% of cases of ovarian cancer attributed to heredity. However, a history of two or more first-degree relatives with ovarian cancer increases an individual’s risk of developing ovarian cancer by greater than 50%.

③ As there are currently no effective screening tools for early detection of ovarian cancer, considerable education efforts have been made to identify patients with the persistence (ie, greater than 2 weeks) of nonspecific presenting symptoms of ovarian cancer including: abdominal pressure/pain, difficulty eating or feeling full quickly, urinary urgency/frequency, change in bowel habits, or unexplained vaginal bleeding.

④ Serum cancer antigen 125 (CA-125) is a nonspecific antigen used as a tumor marker for diagnosing and monitoring epithelial ovarian carcinoma. If CA-125 is positive at the time of diagnosis, changes in CA-125 levels correlate with disease response and progression.

⑤ Although most patients will achieve a complete response to initial treatment, more than 50% of patients will have recurrence within the first 2 years. If recurrence occurs less than 6 months after completion of chemotherapy, the tumor is defined to be platinum-resistant. The antitumor activities of second-line chemotherapy regimens are similar, and the choice of treatment for recurrent platinum-resistant ovarian cancer depends on residual toxicities, physician preference, and patient convenience. Participation in a clinical trial is also a reasonable option for these patients.

⑥ Ovarian cancer is staged surgically with the International Federation of Gynecology and Obstetrics (FIGO) staging algorithm. Tumor-debulking and total abdominal hysterectomy–bilateral oophorectomy surgery are the primary surgical interventions for ovarian cancer. After the completion of the staging and primary surgical treatment, the current standard of care is six cycles of a taxane/platinum-containing chemotherapy regimen.

⑦ Neoadjuvant chemotherapy is intended to reduce tumor burden in preparation for surgery and should be used in patients who are poor surgical candidates because of comorbidities or bulky tumors. The goal of neoadjuvant chemotherapy is to improve the likelihood of optimal tumor debulking.

⑧ A platinum-containing doublet chemotherapy regimen is the standard of care for the first recurrence of platinum-sensitive ovarian cancer.

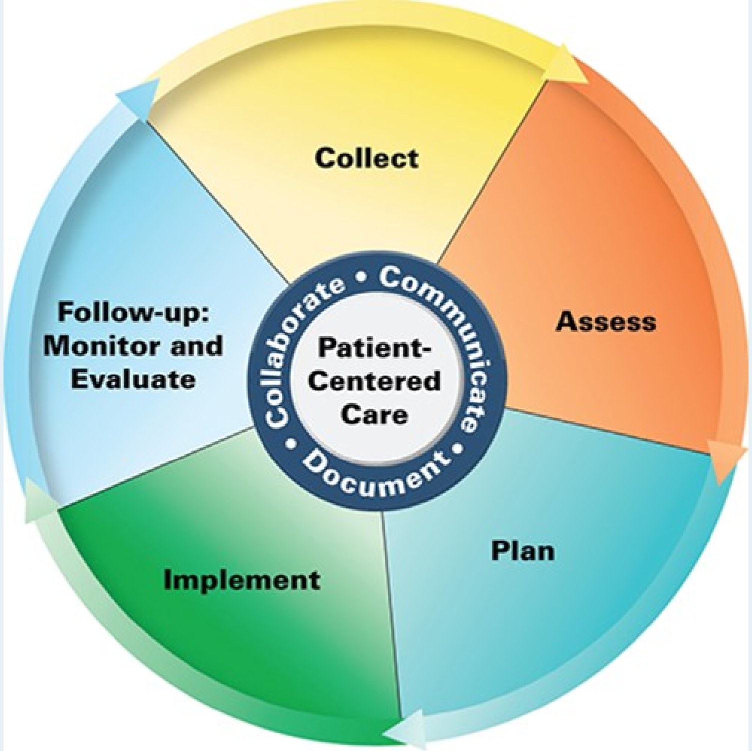
⑨ Despite recent advances, enrollment in an investigational study is still the primary treatment recommendation for patients with recurrent platinum-resistant ovarian cancer.

⑩ Poly(adenosine diphosphate [ADP]-ribose) polymerase (PARP) inhibitors cause double-stranded DNA breaks that cannot be repaired in cancer cells with homologous recombination deficiency, such as those with *BRCA1/2* mutations.

⑪ Patients receiving a platinum or taxane-containing regimen should be monitored for signs of hypersensitivity or infusion-related reactions.

PATIENT CARE PROCESS

Patient Care Process for Ovarian Cancer



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics and medication history, including any allergies
- Medical history, family cancer history, and physical assessment findings
- Patient-specific factors, tumor-specific factors, and laboratory information that may influence chemotherapy selection and drug dosing
- Lifestyle habits, preferences and beliefs, health goals, and socioeconomic factors that affect medication access and other aspects of care

Assess

- Goal of therapy defined by prognosis-based stage of disease and patient preferences
- Medication profile to identify agents that may worsen the patient's symptoms, potential interactions, duplicate therapies, or unnecessary medications. Determine need for symptomatic supportive care medications including antiemetics or pain medications
- Medical and family history to determine whether the patient has compelling indications or contraindications for specific chemotherapy and if additional genetic testing is recommended
- Relevant laboratory tests (eg, CBC, electrolytes, complete metabolic panel to determine liver and hepatic function, tumor markers [eg, CA-125, CEA, and CA19-9 as part of differential], tumor genetic profile) that may impact drug selection or dosing
- Potential appropriate chemotherapy regimens and the related toxicities; review chemotherapy history to determine potential for platinum sensitivity/resistance and consider genetic mutation status in selection of treatment options

Plan*

- Recommendations for any medications or supplements that need to be held temporarily before surgery (eg, anticoagulants, nonsteroidal anti-inflammatory agents, omega 3 fatty acids, etc).
- Anticancer therapy order with dosages based on organ function and patient characteristics (calculate body surface area), list of drug-

interactions and possible adverse drug reactions from the regimen

- Determine whether patient has insurance coverage for planned anticancer therapy regimen and supportive care medications as indicated; consider institution's formulary if applicable
- Recommendations for lifestyle modifications that may assist in symptom and disease management and supportive care options
- Counseling for potential adverse drug reactions of the regimen and management strategies

Implement

- Patient education treatment plan
  - Patients undergoing surgery patients: use of low-molecular weight heparin for postoperative clot prevention, list of medication to stop prior to surgery and when to resume, plan for postoperative pain
  - Patients undergoing anticancer treatment: anticancer therapy agents including timing of administration, expected adverse drug reactions and prevention and management of these toxicities (nausea, infection, neuropathy, alopecia, electrolyte disturbances), necessary laboratory monitoring and follow-up visits; help patient set realistic expectations during treatment

Follow-up: Monitor and Evaluate

- Patients undergoing surgery (2-3 weeks postoperative): evaluate symptom management including nausea, pain control, and determine if adjuvant anticancer therapy is required
- Patients undergoing anticancer therapy:
  - CBC with differential should be obtained prior to each anticancer therapy dose
  - Complete laboratory values should be obtained with each cycle
  - Adjust doses based on unacceptable toxicity or organ dysfunction when indicated.
  - Tumor markers obtained with each cycle: consider reevaluating therapy if a 50% increase or consistent trend upwards
  - Radiographic scan (CT scan/MRI/PET) once every 3 months: assess tumor response, following current RECIST criteria

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Pair up with a classmate and create flashcards of treatment regimens for ovarian cancer on one side and the appropriate line of therapy (first-line following primary surgery, consolidation/maintenance therapy following a complete response with first-line therapy, treatment for relapse greater than 6 months from last platinum therapy, treatment for relapse less than 6 months from last platinum therapy) and common adverse drug reactions of that treatment on the other side. Present your partner with the treatment and have them recommend a patient scenario when that would be an appropriate therapy based on the line of treatment and describe the adverse drug reactions of that regimen. Discuss supportive care interventions to prevent or minimize common adverse drug reactions from the chemotherapy. Compare and contrast your recommendations and discuss other possible situations when the treatment may be considered or any patient-specific factors that may cause you to consider an alternative therapy or recommend dose modifications (eg, avoid bevacizumab in a patient with recent bowel surgery).

INTRODUCTION

① Ovarian cancer is a gynecologic cancer that usually arises from the disruption or mutations in the epithelium of the ovary. It is associated with the highest mortality among the gynecologic cancers, primarily because most patients present with advanced disease. Ovarian cancer is denoted "the silent killer" because of the nonspecific signs and symptoms that often lead to a delayed diagnosis. Ovarian cancers often metastasize via the lymphatic and blood systems to the liver or lungs. Common complications of advanced and progressive ovarian cancer include ascites and small bowel obstruction. Patients who present with disease still confined to the ovary will have a 5-year survival rate greater than 90%, but most patients present with advanced disease and have a 5-year survival rate around 30%.[1] Primary treatment includes tumor-debulking surgery followed by six cycles of a taxane-platinum chemotherapy regimen. Although 70% of patients achieve an initial complete response to chemotherapy, most of these patients will have recurrence within the first 2 years from diagnosis.[2]

EPIDEMIOLOGY

In this chapter, the term "woman" is used to reflect the gender identified in previous research studies and other literature on ovarian cancer and to recognize the biological sex of individuals at birth. In doing so, we recognize that not all patients with ovarian cancer identify as females at the time of diagnosis and treatment of this condition. It is estimated that 19,880 new cases of ovarian cancer were diagnosed and 12,810 women died of the disease in 2022.[1] Unfortunately, despite clinical advances over the past two decades, the overall mortality rate for ovarian cancer is an estimated 60% and has not changed over the past two decades. Ovarian cancer is still associated with the highest mortality rate among the gynecologic cancers and is the fifth leading cause of cancer-related deaths in women. The high mortality rate is related to the insidious onset of nonspecific symptoms and the lack of adequate screening tools, which allows the disease to go undiagnosed until it has progressed beyond the pelvic cavity.

ETIOLOGY

As with many other cancers, the risk of ovarian cancer increases with increasing age. A woman's risk increases from 2.9 to 41.2 per 100,000 as their age advances from less than 40 to 75 years or more, and the median age at diagnosis is 63 years.[3] Most cases of ovarian cancer are diagnosed during the peri- and postmenopausal phase of individual's reproductive life span.

② Heredity accounts for approximately 20% of ovarian cancer cases.[2] Family history of ovarian or breast cancer is an important risk factor in the development of ovarian cancer. If a first-degree relative has a diagnosis of ovarian cancer, the associated lifetime risk is increased by 50%. An individual's risk of ovarian cancer is increased by 10% if a first-degree relative has a diagnosis of breast cancer.[4] Risk is greatest in individuals with multiple family members with ovarian cancer and in those with family members who were diagnosed at an early age.[5]

Breast cancer activator gene 1 *(BRCA1)* and breast cancer activator gene 2 *(BRCA2)* are tumor suppressor genes thought to be involved in one or more pathways of DNA damage recognition and repair. The *BRCA1* gene is located on chromosome 17q12–21 and the *BRCA2* gene is located on chromosome 13q12–13. Both *BRCA1* and *BRCA2* mutations are associated with ovarian cancer. However, *BRCA1* is more prevalent and is associated with 90% of inherited and 10% of sporadic cases of ovarian cancer.[6] Patients with *BRCA1*-associated ovarian cancer are usually considerably younger than patients with *BRCA2* mutations, with a mean age of 54 years.[6] Patients usually present with advanced stage at diagnosis, and the *BRCA1*-linked ovarian cancers are more aggressive tumors that typically are serous histology, moderate-to-high grade. As *BRCA1* and *BRCA2* are thought to be involved in DNA damage or repair, their mutations may be associated with an increased resistance of ovarian cancer cells to cytotoxic agents.

Hereditary breast and ovarian cancer syndrome is one of the two different forms of hereditary ovarian cancer that are associated with germline mutations in *BRCA1* and *BRCA2.* The hereditary nonpolyposis colorectal cancer or Lynch syndrome is a familial syndrome with germline mutations causing defects in enzymes involved in DNA mismatch repair, which is associated with 10% to 15% of hereditary ovarian cancer cases.[7] This syndrome is associated with mutations in DNA mismatch repair genes such as *MSH2, MLH1, PMS1*, and *PMS2* and leads to microsatellite instability.

Hormone exposure, specifically estrogen, and reproductive history is also associated with the risk of developing ovarian cancer. Conditions that increase the total number of ovulations in individual's reproductive history, such as nulliparity, early menarche, or late menopause, are associated with an increased risk for epithelial ovarian cancers.[7] Conversely, those conditions that limit ovulations are associated with a protective effect. Each time ovulation occurs, the ovarian epithelium is broken, followed by cellular repair. According to *incessant ovulation hypothesis*, the risk of mutations and, ultimately, cancer increases each time the ovarian epithelium undergoes cell repair.

Finally, ovarian cancer is associated with certain dietary, lifestyle, and environmental factors. A diet that is high in galactose, animal fat, and meat may increase the risk of ovarian cancer, whereas a vegetable-rich diet may decrease the risk of ovarian cancer.[5] Although controversial, exogenous factors such as asbestos and talcum powder use in the perineal area are also associated with an increased risk of ovarian cancer.[5] Obesity has also been associated with an increased risk of low-grade ovarian cancer in some studies.[5]

PATHOPHYSIOLOGY

Ovarian carcinomas can be separated into three major entities: epithelial carcinomas, germ cell tumors, and stromal carcinomas. Most ovarian tumors (85%-90%) are derived from the epithelial surface of the ovary.[2] The classification of common epithelial tumors has been developed by the World Health Organization and FIGO.[2] The nomenclature considers cell type, location of the tumor, and the degree of the malignancy, which ranges from benign tumors to tumors of low malignancy to invasive carcinomas. Epithelial tumors classified as low malignancy (“borderline malignancy”) are characterized by epithelial papillae with atypical cell clusters, cellular stratification, nuclear atypia, and increased mitotic activity, and have a much better prognosis than those classified as invasive carcinomas. Malignant tumors are characterized by an infiltrative destructive growth pattern with malignant cells growing in a disorganized manner and dissection into stromal planes.

Invasive epithelial adenocarcinomas are characterized by histologic subtype and grade, which measures the degree of cellular differentiation. Although the histologic type of the tumor is not a significant prognostic factor, with the exception of clear cell, the histopathologic grade is an important prognostic factor. Undifferentiated tumors are associated with a poorer prognosis than those lesions that are well or moderately differentiated. A universal grading system for ovarian cancer was developed that combines mitotic score, nuclear atypia score, and architectural score based on the histologic pattern.[8]

The histologic subtypes of ovarian epithelial tumors include serous, mucinous, endometrioid, clear cell, Brenner tumors, mixed epithelial, and undifferentiated carcinomas.[2] High-grade serous carcinoma is the most common type of epithelial ovarian cancer and accounts for about 70% to 80% of cases.[9] The peak age of diagnosis ranges from 55 to 64 years with 63 years as the median age of diagnosis.[3] Endometrioid carcinomas are seen in individuals 40 to 50 years of age and comprise about 8% of ovarian carcinomas, of which about 6% are surface epithelial neoplasms.[10] Endometrioid tumors are usually diagnosed as stage I disease and have a better prognosis than tumors with serous histology. Mucinous carcinomas occur in individuals between 40 and 70 years of age and account for about 36% of all ovarian cancers. The overall prognosis for mucinous carcinoma is better than for serous carcinoma because most patients present with stage I disease. Clear cell carcinoma comprises about 3% of ovarian carcinomas in individuals, with a mean age of 57 years. Although clear cell carcinoma is the least common ovarian neoplasm, it is most commonly associated with paraneoplastic-related hypercalcemia.

Germ cell tumors of the ovary, including malignant teratoma and dysgerminomas, are rare, comprising about 2% to 3% of all ovarian cancers in Western countries with an increased incidence in Black and Asian individuals.[9] These tumors are highly curable and affect primarily young individuals. In contrast to epithelial tumors, about 60% to 70% of germ cell tumors are stage I at diagnosis, which is related to earlier detection and response to symptoms in this younger patient population.[9] Serum markers (human β-chorionic gonadotropin and α-fetoprotein) are helpful to confirm the diagnosis and monitor response to treatment.

Finally, ovarian sex cord-stromal tumors account for 7% of all ovarian cancers and tend to be diagnosed at an early stage.[9] Sex cord-stromal tumors are associated with hormonal effects, such as precocious puberty, amenorrhea, and postmenopausal bleeding. Because these tumors are rare, the optimal treatment of ovarian sex cord-stromal tumors is not clear. The current recommended standard of care is surgery followed by treatment with a platinum-based chemotherapy regimen.

Ovarian cancer is usually confined to the abdominal cavity, but can spread to the lung, liver, and, less commonly, the bone or brain. Direct extension, peritoneal seeding, lymphatic dissemination, or blood borne metastasis spreads disease. Lymphatic seeding is the most common pathway and frequently causes ascites.

SCREENING AND PREVENTION

Screening

③ Ovarian cancer is an uncommon disease with no known preinvasive component, which has made it difficult to detect early disease. In addition, the risk factors for developing ovarian cancer are not well understood, which also makes it difficult to identify a high-risk group of individuals. At the present time, there are no effective screening tools for early detection of ovarian cancer. However, considerable education efforts have been made to identify patients with the persistence of nonspecific presenting symptoms of ovarian cancer including abdominal pressure/pain, difficulty eating or feeling full quickly, urinary urgency/frequency, change in bowel habits, or unexplained vaginal bleeding.

Pelvic examinations are noninvasive and may be able to detect large tumors; however, routine pelvic examinations are not an effective screening tool and do not decrease overall mortality because pelvic examinations cannot detect minimal or microscopic disease.[11]

Transvaginal ultrasound (TVUS) creates an image of the ovary by releasing sound waves. It can be used to evaluate the size and shape and to detect the presence of cystic or solid masses or abdominal fluid. Transvaginal ultrasound can also evaluate blood flow within an ovarian mass. Transvaginal ultrasound is sensitive in identifying ovarian lesions and abnormalities, but its use as a routine screening test is limited by a lack of specificity and an inability to detect peritoneal cancer or cancer in normal-size ovaries.[11]

Serum CA-125 is a nonspecific inflammatory antigen that can be elevated in numerous conditions associated with inflammation in the abdominal cavity. CA-125 has been extensively studied as a potential tumor marker for ovarian cancer based on the observation that CA-125 levels in an individual without ovarian cancer tend to stay the same or decrease over time, whereas levels associated with malignancy tend to gradually increase over time.[11] However, CA-125 is a nonspecific test that can be elevated in a number of benign conditions, including other gynecologic conditions, such as endometriosis, and many nongynecologic conditions, such as diverticulitis and peptic ulcer disease. Because of these limitations, CA-125 levels are not recommended as a routine screening test for detection of ovarian cancer. Numerous other serologic markers such as carcinoembryonic antigen and lipid-associated sialic acid have been evaluated but cannot be recommended for routine screening for ovarian cancer.

The United States Preventive Services Task Force found fair evidence to support screening with CA-125 or TVUS and concluded that earlier detection would likely have a small effect, at best, on mortality from ovarian cancer.[12] Unfortunately, because of the low prevalence of ovarian cancer and the invasive nature of diagnostic testing after a positive screening test, the Task Force also found fair evidence that screening could likely lead to important harms. The United States Preventive Services Task Force concluded that the potential harms outweigh the potential benefits and recommended against any form of routine screening with CA-125 or TVUS for ovarian cancer for asymptomatic individuals who do not have a high-risk hereditary cancer syndrome.

In high-risk individuals, as defined by family history, most clinicians use a multimodality approach for ovarian cancer screening that includes an annual TVUS in combination with a CA-125 blood test every 6 months. Changes in CA-125 are monitored over time, and changes such as a persistent elevation or consistent increases in CA-125 levels in conjunction with TVUS abnormalities are evaluated further.

Prevention

It is difficult to make recommendations for prevention for the general population because ovarian cancer is a sporadic disease with no established risk factors. Noninvasive measures, such as chemoprevention, can decrease the risk of developing ovarian cancer. Ovulation itself is considered a potential insult to the ovarian epithelium, increasing its susceptibility to damage and, ultimately, to cancer. Interventions or reproductive conditions associated with decreasing the number of ovulations, including multiparity, may have a protective effect for the prevention of ovarian cancer. However, the more invasive prevention interventions, such as prophylactic surgery and genetic screening, should be reserved for those individuals identified to be at high risk based on their inherited risk for developing ovarian cancer.

Although a number of agents have been investigated as chemoprevention of ovarian cancer, including oral contraceptives, aspirin, nonsteroidal anti-inflammatory agents, and retinoids, none of these agents is currently accepted as a standard treatment for the prevention of ovarian cancer. Oral contraceptives may be considered for patients at high risk of ovarian cancer as they inhibit ovulation, which reduces the potential for damage to the ovarian epithelium. When taken for longer than 10 years, oral contraceptives decrease the relative risk to less than 0.4.[13] Because oral contraceptive use has been associated with an increased risk of breast cancer, individuals with a family history of breast cancer should carefully consider the use of oral contraceptives as chemoprevention of ovarian cancer, though modern oral contraceptives are far less likely to increase the risk of breast cancer than those used prior to 1975.[13]

Prophylactic Surgery

Prophylactic surgical interventions for the prevention of ovarian cancer are reserved for patients with a significant family history or known genetic mutations such as *BRCA1* and should be postponed until after childbearing is completed, preferably between the ages of 35 to 40 years.[14] The goal is to remove healthy, at-risk organs before any carcinogenic activity is initiated, ultimately reducing the risk of developing cancer. These surgeries include prophylactic oophorectomy or bilateral salpingo-oophorectomy and tubal ligation. These procedures cause surgical menopause, which can be associated with severe hot flashes, vaginal dryness, sexual dysfunction, and increased risk for development of osteoporosis and heart disease. Because of the potential impact on quality of life and increased health risks, prophylactic surgery is not recommended as a general prevention intervention.

Although prophylactic surgical interventions are the most effective way to reduce the risk of developing ovarian cancer in high-risk populations, patients who choose to have a prophylactic oophorectomy/bilateral salpingo-oophorectomy need to be informed that complete protection is not guaranteed.[13–15] Although a 67% risk reduction has been shown, a potential 2% to 5% risk of primary peritoneal cancer remains.[15] Primary peritoneal cancers have identical histology of ovarian tumors with diffuse involvement of peritoneal surfaces. Primary peritoneal cancers can often result from "seeding" during the prophylactic surgery. It is recommended for peritoneal washings to be completed during the prophylactic surgery to check for the presence of tumor cells on peritoneal surfaces. If positive, then prophylactic surgery would change to staging and treatment surgery to determine extent of disease and remove any other possible lesions.

Tubal ligation is another procedure that can reduce the risk for developing ovarian cancer. In a case-control study, Narod and colleagues[16] reported that tubal ligation in *BRCA*-positive patients was associated with a 63% reduction in risk of developing ovarian cancer. However, it is not recommended as a sole procedure in prophylaxis. The mechanism for its protective effect is not clear, but it has been proposed that tubal ligation may limit exposure of the ovary to environmental carcinogens.

Genetic Screening

Genetic screening should be considered for all individuals who are suspected of carrying a BRCA mutation, based on family history or young age (less than 50 years old) at diagnosis and a high-grade serous tumor. Patients should be evaluated for the presence of genes such as *BRCA1*, *BRCA2*, or other genes such as those associated with hereditary nonpolyposis colorectal cancer or the hereditary breast ovarian cancer (hereditary breast and ovarian cancer syndrome) syndrome.[16] Prior to genetic screening, appropriate patient/family counseling and genetic counseling should be available to help individuals prepare and deal with the health and psychosocial implications of the genetic screening results.

CLINICAL PRESENTATION

Patients with early ovarian cancer are often asymptomatic and the ovarian mass is detected incidentally during an unrelated surgery, procedure, or imaging. Patients with ovarian cancer often present with nonspecific, vague symptoms such as abdominal bloating, pressure or pain, indigestion, or change in bowel movements.[2] These symptoms can easily be confused with symptoms of common benign gastrointestinal disorders. Patients will often not seek medical attention until these symptoms become unrelenting and bothersome, which allows the disease to progress undetected. Patients with advanced disease may report symptoms such as pain, abdominal distension, and ascites.[2]

Several groups have partnered together to educate individuals about early signs and symptoms of ovarian cancer. Goff and colleagues[17] developed a symptom index, based on a comparison of symptoms experienced in patients with ovarian cancer and a matched control group. Symptoms that were correlated with ovarian cancer include persistent or recurrent bloating, pelvic or abdominal pain, difficulty eating or feeling full quickly, and urinary symptoms (either urgency or frequency). The Gynecologic Cancer Foundation, Society of Gynecologic Oncologists, and American Cancer Society recommend that individuals who have any of those problems nearly every day for more than 2 weeks should see a gynecologist, especially if the symptoms are new and quite different from the usual state of health. Furthermore, healthcare professionals should keep ovarian cancer in the differential for patients presenting with these persistent symptoms.

The diagnostic workup for suspected ovarian cancer includes a careful physical examination including a Papanicolaou, or Pap, smear and a pelvic and rectovaginal examination.[18] The presence of a pelvic mass that is unilateral or bilateral, solid, irregular, fixed, or nodular is highly suggestive of ovarian cancer. Unfortunately, by the time a pelvic mass can be palpated on physical exam, the disease would have already advanced beyond the pelvic cavity. A detailed family history should be taken, especially noting the number and pattern of first-degree relatives with malignancies. All patients with suspected ovarian malignancies should be referred to a gynecologic oncologist for evaluation as survival is increased when primary assessment and surgery is performed by a specialist.[19]

④ A complete blood count, chemistry profile (including liver and renal function tests), and CA-125, carcinoembryonic antigen, or CEA, and cancer antigen 19-9, or CA19-9, levels should be performed. Although CA-125 is a nonspecific antigen, it is the best current tumor marker for epithelial ovarian carcinoma.[18] A normal CA-125 value is less than 35 units/mL (kU/L). If the CA-125 is elevated at the time of diagnosis, changes in CA-125 levels correlate with tumor burden. Rising CA-125 levels are often associated with disease progression, but CA-125 can be elevated in various other conditions such as different phases of the menstrual cycle, diverticulitis, endometriosis, as well as other nongynecologic cancers. When a patient presents with an abdominal mass, it is important to rule out other cancers in the abdominal cavity. Carcinoembryonic antigen and CA19–9 are markers for other gastrointestinal cancers and may be helpful in the differential diagnosis.

Other diagnostic tests should include a TVUS or abdominal ultrasonography, chest radiography, computed tomography, magnetic resonance imaging, or positron emission tomography scan. An upper gastrointestinal series, intravenous pyelogram, cystoscopy, proctoscopy, or barium enema is sometimes indicated to confirm diagnosis and extent of disease.

CLINICAL PRESENTATION: Ovarian Cancer

General

- Ovarian cancer is sometimes referred to as “the silent killer” because of the vague nonspecific signs and symptoms that contribute to the delay in diagnosis.

Symptoms

- The patient may complain of abdominal discomfort, nausea, dyspepsia, flatulence, bloating, fullness, early satiety, urinary frequency, change in bowel function (diarrhea or constipation), weight change, and digestive disturbances.

Signs

- Abdominal or pelvic mass may be palpable.
- Lymphadenopathy may be present.
- Vaginal bleeding may be irregular.
- Patient may have signs of ascites (abdominal distension, shifting, and dullness to percussion—may present like “pregnant abdomen”).

Laboratory Tests

- CA-125 may be elevated (normal level is <35 units/mL [kU/L]).
- Abnormalities in liver function tests may suggest hepatic involvement.
- Abnormalities in renal function tests may suggest compression of the renal system by the tumor.

TREATMENT

Desired Outcomes

The goals of treatment of ovarian cancer depend upon the FIGO stage at diagnosis. While ideally "treatment for cure" is desired, it is important to set realistic expectations for the patient. Most patients will achieve a complete response to the initial multimodality treatment, but over 75% of these patients will have disease recurrence.[20] Although overall survival has not significantly changed for ovarian cancer patients, progression-free survival has improved, which translates to less time on chemotherapy and overall improvement in quality of life for these patients.

In patients who present with metastatic disease or are not surgical candidates, the goal of treatment is to alleviate symptoms and prolong survival as long as quality of life is acceptable. In the setting of recurrent platinum-resistant ovarian cancer, the treatment goal is also to alleviate symptoms and prolong survival as long as quality of life is acceptable.

General Approach

⑤ A multimodal approach that includes comprehensive surgery and chemotherapy is used for the initial treatment of ovarian cancer with curative intent. Although most patients will initially achieve a complete response, more than 50% will recur within the first 2 years.[21] A clinical complete response to treatment is defined as no evidence of disease by physical examination or diagnostic tests and a normal CA-125 level.

Chemotherapy regimens for ovarian cancer have evolved over the past several decades to the current standard of care for first-line treatment that includes a taxane- and platinum-based regimen. Certain subgroups of patients have a better or worse response to chemotherapy. The histologic subtype of the tumor is a prognostic factor; clear cell histology is more likely to be poorly differentiated, faster growing, and have intrinsic drug resistance.[2,9] However, the extent of residual disease, size larger than 1 cm, and tumor grade are better predictors of response to chemotherapy and overall survival.[2] In general, younger patients have a better performance status and tolerate chemotherapy better than older adult patients. For unknown reasons, white women tend to have a worse prognosis and response to therapy as compared with women of other ethnic backgrounds.[2]

In patients with recurrent ovarian cancer, the goals of treatment are to relieve symptoms such as pain or discomfort from ascites, slow disease progression, and prevent serious complications such as small bowel obstructions.

Surgery

Surgery is the primary treatment intervention for ovarian cancer.[22–24] Surgery may be curative for selected patients with limited stage IA disease. Primary surgical treatment includes a total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH/BSO), omentectomy, and lymph node dissection (Fig. 156-1).[22–24] The primary objective of the surgery is to optimally debulk the tumor to remove all gross disease.[18] Long-term follow-up studies confirm that residual disease smaller than 1 cm correlates with higher complete response rates to chemotherapy and longer overall survival as compared to patients with bulky residual disease (>1 cm).[23]

⑥ A comprehensive exploratory laparotomy is vital for the accurate confirmation of diagnosis and staging of ovarian cancer.[22,23] Unlike other cancers that are typically diagnosed by biopsy or laboratory results and clinically staged by results from imaging tests, gynecologic cancers are surgically diagnosed and then staged according to the FIGO staging algorithm (Fig. 156-2). The FIGO staging system requires an extensive surgery by an experienced gynecologic oncologist. The training and skill of the surgeon has a significant effect on prognosis, with definitive benefit of a trained gynecologic oncologist performing surgery as compared with a gynecologist or general surgeon.[19,25] The reasons for this approach include (a) pelvic tumors cannot be readily biopsied without risk of “tumor seeding,” which can increase the risk of recurrence, and (b) surgical staging takes into account the presence of microscopic disease in samples obtained by pelvic washing and lymph node dissection and read by a pathologist during the surgical procedure. It is recommended that the initial surgical staging and tumor-debulking surgery be completed by a trained gynecologic oncology surgeon when ovarian cancer is suspected to prevent understaging and to optimize overall outcome.[18,19,22,26]

Secondary cytoreduction or interval debulking is when surgery is performed after completion of some or all chemotherapy to remove residual disease. Some protocols include additional cycles of chemotherapy after the surgical procedure. The importance of cytoreduction before, during, or after chemotherapy is still controversial, but it has been recommended to facilitate response to chemotherapy and improve overall survival.[18] Randomized trials of secondary surgical cytoreduction have reported conflicting results. In a study of 550 women with stage III or IV disease treated with primary cytoreductive surgery and three cycles of paclitaxel and cisplatin, patients randomized to receive secondary cytoreductive surgery followed by three more cycles of chemotherapy had similar progression-free survival and overall survival as compared with those randomized to receive three more cycles of chemotherapy alone.[27]

The overall effect of interval debulking is influenced by several factors, including initial response to chemotherapy, the amount of residual disease before and after second-look surgery, and the presence of microscopic residual disease. The results of recent trials suggest that secondary surgical cytoreduction does not prolong survival in patients who are treated with maximal primary cytoreductive surgery followed by appropriate postoperative chemotherapy.[28]

“Second-look surgery” is an elective surgical procedure performed in patients who achieve a clinical complete response after primary chemotherapy to determine if any visible or microscopic disease is present in the peritoneal cavity. The benefit of “second-look laparotomy” to evaluate residual disease after completing chemotherapy remains controversial because it has been difficult to establish any impact on overall survival. It has questionable benefit because about 50% of those with a negative second look still relapsed.[27] If visible or microscopic disease is detected during second look, then the clinician may decide to give additional chemotherapy. But if no visible or microscopic disease is detected during second look, the clinician may decide to observe and monitor the patient. Use of laparoscopic surgical techniques is controversial for initial surgery but is sometimes considered in debulking of recurrent or advanced disease when the intent is palliative rather than curative.[24] In patients with recurrent disease, the goal of debulking surgery is to relieve symptoms associated with complications such as small bowel obstructions and to improve the patient's quality of life.

Radiation Therapy

Radiation therapy has a limited role in the management of ovarian cancer. Use of radiation therapy for treatment of early stage disease has no impact on overall survival.[29] Radiation therapy is most beneficial for palliation of symptoms in patients with recurrent pelvic disease, often associated with small bowel obstructions. The two forms of radiation therapy used in ovarian cancer are external beam whole-abdominal irradiation and intraperitoneal isotopes such as phosphorus-32, or ^{32}P. Alleviation of symptoms with external beam whole-abdominal irradiation is associated with a significant improvement in the patient's quality of life. The recommended dose ranges from 35 to 45 Gy (3,500-4,500 rad), depending on the treatment history and ability to tolerate radiation treatments.

First-Line Chemotherapy

The mainstay of ovarian cancer treatment is chemotherapy. It is used as a component of first-line treatment after completion of surgery and is the primary modality of treatment for recurrent ovarian cancer. Systemic chemotherapy with a taxane and platinum regimen following optimal surgical debulking is the standard of care for treatment of epithelial ovarian cancer (Fig. 156-3).[18] Table 156-1 summarizes the chemotherapeutic regimens used as the initial treatment of newly diagnosed epithelial ovarian cancer. More than 60 randomized controlled clinical trials have evaluated combination chemotherapy regimens for the treatment of advanced ovarian cancer, and a meta-analysis of these trials confirms the efficacy of platinum and taxane regimens over other regimens.[30]

TABLE 156-1

Initial Chemotherapeutic Regimens of Epithelial Ovarian Cancer

Regimen	Initial Dose(s)/Usual Range	Cycle Frequency
Paclitaxel + carboplatin	Paclitaxel 175 mg/m^2 IV (3-hour infusion) day 1	Every 21 days
	Carboplatin AUC 5–6 IV day 1	
Paclitaxel + carboplatin + bevacizumab	Paclitaxel 175 mg/m^2 IV (3-hour infusion) day 1	Every 21 days
	Carboplatin AUC 5-6 IV day 1	
	Bevacizumab 7.5-15 mg/kg IV on day 1	
Paclitaxel + carboplatin (dose-dense)	Paclitaxel 80 mg/m^2 IV (1-hour infusion) on days 1, 8, 15	Every 21 days
	Carboplatin AUC 5-6 IV day 1 or AUC 2 on days 1, 8, and 15	
Paclitaxel + cisplatin (IP)	Paclitaxel 135 mg/m^2 IV infused over 24 hours on day 1	Every 21 days
	Cisplatin 100 mg/m^2 IP infused over 1 hour on day 2	
	Paclitaxel 60 mg/m^2 IP infused over 1 hour on day 8	
Carboplatin + pegylated liposomal doxorubicin	Carboplatin AUC 5 IV day 1	Every 28 days
	Pegylated liposomal doxorubicin 30 mg/m^2 IV day 1	
Docetaxel + carboplatin	Docetaxel 75 mg/m^2 IV day 1	Every 21 days
	Carboplatin AUC 5-6 IV day 1	

Single-agent alkylating agents such as melphalan, and later cyclophosphamide, were used for the treatment of advanced ovarian cancer until cisplatin was introduced in the 1970s. Combination chemotherapy regimens containing cisplatin and cyclophosphamide achieved higher response and overall survival rates than regimens without cisplatin in patients with advanced ovarian cancer.[31] Based on the results of these trials, the combination of cisplatin plus cyclophosphamide remained the standard of care for the treatment of ovarian cancer until the early 1990s.

The combination of paclitaxel (135 mg/m^2 over 24 hours) and cisplatin (75 mg/m^2) has been an accepted standard of care for the treatment of ovarian cancer because of its effectiveness since the early 1990s. It is associated with a median progression-free survival of 18 months and overall survival of 38 months from the Gynecologic Oncology Group (GOG)-11 and OV10 studies.[32,33] Neutropenia, alopecia, and peripheral neuropathy are common adverse drug reactions.

Carboplatin can be substituted for cisplatin, which spares patients from the significant nephrotoxicity and peripheral neuropathy associated with cisplatin. Several prospective randomized comparisons of carboplatin plus paclitaxel versus cisplatin plus paclitaxel in patients with advanced ovarian cancer have been conducted have shown carboplatin plus paclitaxel is equally efficacious and better tolerated than cisplatin and paclitaxel.[34–37] As expected, the incidence of nausea and vomiting, nephrotoxicity, and peripheral neuropathy is higher in patients in the cisplatin arm, while patients in the carboplatin arm experienced more thrombocytopenia. Based on these results, paclitaxel plus carboplatin is the preferred standard-of-care regimen.

While most chemotherapy drugs used to treat ovarian cancer are dosed according to body surface area, or BSA, carboplatin dosing is personalized based on each individual's renal function with the Calvert formula: carboplatin dose = area under the curve (AUC) × (glomerular filtration rate [GFR] + 25).[38] When it was originally developed and validated, measured GFR was used in the Calvert equation. However, estimated creatinine clearance (CrCl) is now used in clinical practice in place of measured GFR. Despite more than 30 years of clinical use, it is still not clear which equation to use to estimate CrCl and the best method to estimate CrCl in certain patient subgroups. The use of personalized carboplatin dose has reduced potential toxicity such as thrombocytopenia, neuropathy, and nephrotoxicity.[38] Personalized dosing of carboplatin is one of the reasons why it is the preferred platinum agent over cisplatin for primary treatment for ovarian cancer.[36]

Similarly the use of docetaxel as a substitute for paclitaxel has been evaluated as paclitaxel can cause significant peripheral neuropathy over time. The results of the Scottish Randomized Trial in Ovarian Cancer, or SCOTROC, study showed that the substitution of docetaxel for paclitaxel does not compromise efficacy and improves tolerability, particularly neurotoxicity, but patients receiving docetaxel experienced more grade 3 to4 neutropenia and neutropenic complications.[39] These findings were not confirmed in another randomized controlled trial. However, based on the results of this study, the combination of docetaxel plus carboplatin is considered a reasonable treatment option for patients with advanced ovarian cancer. Docetaxel and paclitaxel both cause alopecia and have a risk of infusion-related reactions or true hypersensitivity reactions, though reactions are more common with paclitaxel. Paclitaxel infusions require premedication with a corticosteroid, diphenhydramine, and a H_2-blocker like famotidine to help prevent severe reactions. Due to the risk of fluid retention with docetaxel, premedication with dexamethasone is recommended to reduce the incidence and severity. Six cycles of paclitaxel plus carboplatin following tumor-debulking surgery remain the current standard of care for treatment of advanced ovarian cancer. Although the choice of taxane or platinum agent does not appear to have a major effect on antitumor activity, the impact of paclitaxel dose and frequency of administration has been controversial.[40–42] Due to less favorable treatment-related toxicities and questionable benefit on progression-free survival, dose-dense weekly paclitaxel regimens are not widely used.

Intraperitoneal (IP) chemotherapy was initially employed as palliative care in the management of ascites and uncontrolled intra-abdominal tumors based on the rationale that exposure of the tumor to high drug concentrations would increase tumor drug uptake by passive diffusion and ultimately cancer cell death.[43] The increase in AUC exposure in the peritoneal cavity was demonstrated, but the correlative increase in drug uptake in tumor tissue has yet to be validated in any preclinical or clinical study.

IP chemotherapy has demonstrated benefit in the first-line treatment of patients with optimally debulked advanced-stage ovarian cancer.[44,45] In a landmark GOG-172 study, which evaluated the intravenous combination regimen of paclitaxel (135 mg/m^2 over 24 hours) and cisplatin (75 mg/m^2) or a new combination regimen that included intravenous paclitaxel (135 mg/m^2 over 24 hours) followed by cisplatin 100 mg/m^2 IP infused over 1 hour on day 2, and then paclitaxel 60 mg/m^2 IP infused over 1 hour on day 8.[46] Both treatment regimens were given once every 21 days for a total of six cycles. Patients receiving IP chemotherapy experienced a 5.5-month increase in median progression-free survival and a 15.9-month increase in overall survival.[46] A secondary analysis by Tewari and colleagues[47] of patients from GOG-172 and GOG-114 IP therapy studies reported a 10.4 month improvement in the median overall survival and 23% decreased risk of death in those patients that had received IP chemotherapy compared to IV chemotherapy. Contributing factors that negatively impacted survival included gross residual disease, clear cell or mucinous histology, and not completing all six cycles of IP chemotherapy.

A limitation of IP therapy is significantly more toxicity, including pain, fatigue, myelosuppression, gastrointestinal, metabolic, and neurotoxicity.[18,46,48,49] The significant increase in systemic toxicity, primarily neurotoxicity, has led to the question of whether IP carboplatin could be substituted for IP cisplatin. Although these platinum agents have demonstrated equal efficacy when administered intravenously (IV) to ovarian cancer patients, it is difficult to extrapolate the IP activity of cisplatin to carboplatin because of the difference in molecular size of cisplatin versus carboplatin and the importance of passive diffusion of drug into the tumor. Most clinical trials used platinum agents given IP until the GOG-172 trial that incorporated IP paclitaxel. Many clinicians are concerned about how to manage hypersensitivity reactions to either platinum or taxane agents when administered IP.

In the National Comprehensive Cancer Network (NCCN) guidelines, IP chemotherapy is an option for first-line treatment of stage II to III, optimally debulked, <1 cm residual disease, ovarian cancer but is not without clinical controversy.[18] Because of the significant toxicities associated with IP therapy, only carefully selected patients should receive IP therapy. Ideal candidates for IP therapy are younger patients with good performance status, minimal comorbidities, adequate renal and liver function, and optimally debulked disease without significant bowel resection.[18,49] The IP regimens have recently fallen out of favor due to the results of GOG-252. Bevacizumab was administered in combination with IV/IP paclitaxel and carboplatin compared to IV/IP paclitaxel and cisplatin, or IV paclitaxel and carboplatin.[50] With the addition of bevacizumab to first-line chemotherapy, no progression-free or overall survival benefit with IP administration was observed and the IV regimen was as effective and better tolerated.[50]

Neoadjuvant Chemotherapy

⑦ Neoadjuvant chemotherapy is first-line treatment for patients who are poor surgical candidates or patients with bulky or significant tumor burden.[51] The neoadjuvant chemotherapy regimen typically includes a combination of taxane with platinum agent and is administered every 21 to 28 days as tolerated with intent to reduce tumor burden to where it potentially could be surgically resected and ideally optimally debulked during surgery.[51] After surgery, patients usually receive another three to six cycles (IV or IP/IV), depending on their response to chemotherapy.[18,52] In patients who are poor candidates for surgery because of comorbidities, the primary intent of neoadjuvant chemotherapy is to relieve symptoms and slow disease progression. In this setting, palliative chemotherapy alone has not been curative for patients with advanced ovarian cancer.[51] If tolerated, these patients will receive the standard taxane plus platinum chemotherapy regimen once every 3 to 4 weeks. Another option for palliative neoadjuvant chemotherapy, especially in older adult patients, is single-agent carboplatin once every 4 weeks.

Consolidation Therapy and Maintenance Therapy

Consolidation therapy is given to patients without “measurable disease” after the completion of primary chemotherapy, with the goal of eliminating any microscopic residual disease that may be present to extend progression-free and overall survival. It will have a set duration to therapy and typically is less toxicity than primary chemotherapy regimens. Patients undergoing consolidation therapy are monitored for signs of recurrent disease. Maintenance therapy, however, is given to patients with measurable disease, with the goal of prevent progression/growth of disease. It is given for an undetermined duration and may alternate or “switch maintenance” between aggressive cytotoxic regimens and less toxic regimens. Patients undergoing maintenance therapy are monitored for clinical response or progression of disease. Both bevacizumab and PARP inhibitors are the only agents approved by the US Food and Drug Administration for use as consolidation in the first-line setting however mislabeled as “first-line maintenance”. For the purpose of this chapter, this therapy will be referred to consolidation because there is no measurable disease and it is administered for a defined two year duration.

Consolidation with bevacizumab and/or PARP inhibitor therapy is recommended by the NCCN guidelines following first-line treatment depending on the agents used as first-line therapy and the patient’s mutation status (category 2A recommendation).[18] Single-agent bevacizumab is recommended as consolidation therapy only if it was used with first-line chemotherapy based on GOG-0218 and ICON7.[18] No data exists to support bevacizumab consolidation if it was not used with first-line chemotherapy.

Olaparib, an oral PARP inhibitor, should be considered as consolidation therapy in individuals with a germline mutation in *BRCA1* or *BRCA2* and a response to first-line platinum-based therapy. Continuous twice-daily oral dosing of olaparib provides substantial clinical benefit in progression-free survival when compared to placebo.[53] The use of consolidation therapy with olaparib results in a 70% lower risk of disease progression or death. Niraparib, another PARP inhibitor, should also be considered as consolidation because it improves progression-free survival by 5.6 months (13.8 months compared to 8.2 months with placebo).[54] This effect is more pronounced in patients with *BRCA* or other homologous recombination repair gene mutations. The NCCN guidelines recommend niraparib as an option for those who are *BRCA1/2* wild-type or unknown who did not receive bevacizumab with primary treatment and as an option for patients with a *BRCA1/2* mutation.[18]

Bevacizumab in combination with olaparib was studied as consolidation following frontline chemotherapy with bevacizumab in patients with homologous recombination repair gene mutations, including those without *BRCA* mutations, in the PAOLA-1 study.[55] The addition of olaparib to bevacizumab resulted in a 51% risk reduction in disease progression or death compared to bevacizumab alone.[55] One major limitation of this study is that it did not include an arm with olaparib alone, so the addition of bevacizumab to olaparib compared to single-agent olaparib is unknown.

The clinical challenge with consolidation therapy after first-line treatment is selection of which agent based on molecular profile and cost of therapy. Patients need to be evaluated for tumor molecular status, residual toxicity, renal function, and co-morbidities to determine if bevacizumab or PARP inhibitor or perhaps combination of bevacizumab plus PARP inhibitor would be the best option for consolidation. However, from the cost perspective neither bevacizumab nor PARP inhibitors are cost effective for consolidation therapy after completion of primary treatment of ovarian cancer.[56]

Treatment of Recurrent Disease

Although most patients will achieve a complete response to initial treatment, most patients will eventually have recurrence of their disease within the first 2 years. When a patient relapses, the prognostic factors are similar to the factors after initial surgery except that the disease-free interval—defined as the length of time that has lapsed since the completion of chemotherapy—should be considered to determine if the tumor is likely to be drug resistant to agents used in first-line treatment (ie, platinum and taxanes). If recurrence occurs less than 6 months after completion of chemotherapy or if the patient progresses during platinum-based chemotherapy, the tumor is defined as platinum-resistant. Patients with platinum-sensitive disease generally have a better prognosis than platinum-resistant patients.

⑧ ⑨ If the patient had a clinical complete response to first-line chemotherapy and the recurrence occurred more than 6 months after chemotherapy is completed, the tumor is considered platinum-sensitive. In patients with platinum-sensitive ovarian cancer, the standard of care is to treat the first recurrence with a doublet, platinum-containing chemotherapy regimen (Table 156-2). Because the chemotherapy agents used for second-line treatment of recurrent or refractory platinum-resistant disease have similar response rates that average less than 30%, the selection of the agent depends on the toxicity profile of the agent, physician preference, patient performance status, residual toxicities, and patient convenience (see Fig. 156-3). In this setting, the intent of treatment is to prolong survival and alleviate symptoms, not necessarily and unlikely to achieve another "complete response" to chemotherapy. Because of poor response rates of the available agents, participation in a clinical trial of an investigational agent is recommended if available for patients with recurrent platinum-resistant ovarian cancer.

TABLE 156-2

Chemotherapy Regimens for Platinum-Sensitive Recurrent Ovarian Cancer

Regimen	Initial Dose(s)/Usual Range	Cycle Frequency
Carboplatin + gemcitabine	Carboplatin AUC 5 IV day 1	Every 21 days

Carboplatin + gemcitabine + bevacizumab	Carboplatin AUC 5 IV day 1	Every 21 days
	Gemcitabine 800 mg/m^2 IV day 1 & 8	
	Bevacizumab 15 mg/kg IV day 1	
Carboplatin + pegylated liposomal doxorubicin	Carboplatin AUC 5 IV day 1	Every 28 days
	Pegylated liposomal doxorubicin 30 mg/m^2 IV day	
Carboplatin + pegylated liposomal doxorubicin + bevacizumab	Carboplatin AUC 5 IV day 1	Every 28 days
	Pegylated liposomal doxorubicin 30 mg/m^2 IV day	
	Bevacizumab 15 mg/kg IV day 1 & 15	
Carboplatin + paclitaxel	Carboplatin AUC 5-6 IV day 1	Every 21 days
	Paclitaxel 175 mg/m^2 IV day 1	
Carboplatin + paclitaxel + bevacizumab	Carboplatin AUC 5-6 IV day 1	Every 21 days
	Paclitaxel 175 mg/m^2 IV day 1	
	Bevacizumab 15 mg/kg IV day 1	
Cisplatin + gemcitabine	Cisplatin 30 mg/m^2 IV day 1 & 8	Every 28 days
	Gemcitabine 600-750 mg/m^2 IV day 1 & 8	
Bevacizumab	Bevacizumab 10 mg/kg on days 1 and 15 or	Every 28 days
	Bevacizumab 15 mg/kg IV on day 1	Every 21 days
Olaparib	300 mg PO twice daily	
Niraparib	300 mg PO daily	
Rucaparib	600 mg PO twice daily	

PO, by mouth.

Platinum-Sensitive Disease

8 Retreatment with a platinum-containing regimen should be considered in patients with platinum-sensitive disease. The 2021 NCCN guidelines recommend the combination of platinum agent with gemcitabine, pegylated liposomal doxorubicin, or paclitaxel for treatment of platinum-sensitive recurrent ovarian cancer (Table 156-3).[18] In addition, the combination of gemcitabine plus cisplatin, gemcitabine plus carboplatin and bevacizumab and carboplatin plus paclitaxel and bevacizumab has demonstrated improvement in progression-free survival.[57–59] Carboplatin alone or any of the second-line agents is recommended for patients with platinum-sensitive disease who are unable to tolerate additional combination chemotherapy regimens because of residual toxicity or poor performance status.

TABLE 156-3

Chemotherapy Regimens for Platinum-Resistant Recurrent Ovarian Cancer

Drug(s)	Initial Dose(s)/Usual Range	Cycle Frequency
Paclitaxel + bevacizumab	Paclitaxel 60-80 mg/m^2 IV days 1, 8, 15, and 22	Every 28 days
	Bevacizumab 10 mg/m^2 IV days 1 and 15	
Paclitaxel	60-80 mg/m^2 IV days 1, 8, 15, and 22	Every 28 days
Pegylated liposomal doxorubicin + bevacizumab	Pegylated liposomal doxorubicin 40 mg/m^2 IV day 1	Every 28 days
	Bevacizumab 10 mg/m^2 IV days 1 and 15	
Pegylated liposomal doxorubicin	40 mg/m^2 IV day 1	Every 28 days
Topotecan + bevacizumab	Topotecan 3-4 mg/m^2 IV days 1, 8, and 15	Every 28 days
	Bevacizumab 10 mg/m^2 IV days 1 and 15	
Topotecan	3-4 mg/m^2 IV days 1, 8, and 15	Every 28 days
Gemcitabine	800 mg/m^2 IV day 1 & 8	Every 21 days
Docetaxel	100 mg/m^2 IV day 1	Every 21 days
Etoposide (oral)	50 mg/m^2 PO daily on days 1-21	Every 28 days
Cyclophosphamide (oral) + bevacizumab	Cyclophosphamide 50 mg PO once daily	Every 28 days
	Bevacizumab 10 mg/kg on days 1 and 15	
Bevacizumab	10 mg/kg on days 1 and 15 OR	Every 28 days
	15 mg/kg IV on day 1	Every 21 days
Olaparib	300 mg PO twice daily	
Niraparib	300 mg PO daily	
Rucaparib	600 mg PO twice daily	

Biologic and targeted agents play an important role in the treatment of recurrent disease. Bevacizumab is a recombinant humanized monoclonal antibody that targets vascular endothelial growth factor (VEGF), a key mediator of angiogenesis. In patients with platinum-sensitive recurrent disease, the addition of bevacizumab to chemotherapy (eg, carboplatin/gemcitabine, carboplatin/paclitaxel) improves disease outcomes.[58,59] Due to the toxicity profile of bevacizumab, patients considered for bevacizumab therapy must be carefully selected. Further details regarding the role of bevacizumab and other targeted and biologic agents in the treatment of ovarian cancer will be discussed in the following section.

The preferred regimen for platinum-sensitive recurrent disease varies by clinician. Some clinicians will recommend retreatment with a chemotherapy regimen including a platinum agent. Other clinicians suggest that the platinum-free interval for these patients should be extended and recommend that recurrent disease first be treated with a nonplatinum regimen (ie, liposomal doxorubicin) and reserve the platinum agent until the next relapse.

Platinum-Resistant Disease

Patients frequently present with recurrent drug-resistant disease after initial platinum-based therapy and cytoreductive surgery.[2] Patients who progress on a platinum agent or have no response are considered “platinum-refractory,” while those patients who have recurrence within 6 months of completing a platinum-containing regimen are considered “platinum-resistant.”[18] The NCCN guidelines list many possible treatment options for recurrent platinum-resistant or refractory ovarian carcinoma.[18] The optimal chemotherapeutic agent or regimen in the treatment of platinum-resistant disease is unclear. Ideally, the agent should be active in ovarian cancer and non–cross-resistant with taxanes or platinum agents. Unfortunately, the response rate is low for all agents in platinum-refractory or resistant ovarian cancer.[2] Patients should typically be evaluated for response after treatment with at least three cycles of the chemotherapy agent or regimen. Because partial responses are rare, stable disease with relief of symptoms is considered a treatment success. If no response is observed, then an alternative chemotherapy regimen may be selected. Because all the potential agents have similar efficacy, the selection of agents and sequence used for treatment as the patient progresses will vary based on residual toxicity **and the adverse effect profile of the regimen (Table 156-4),** dosing schedule, patient convenience, and physician preference.

TABLE 156-4

Adverse Drug Reactions of Treatments for Ovarian Cancer

Class	Drug	Common Adverse Drug Reactions
Taxane agents	Paclitaxel	Peripheral neuropathy (DLT), nausea/vomiting, alopecia, hypersensitivity reactions
	Docetaxel	Neutropenia (DLT), fluid retention, nail disorders, myelosuppression, alopecia
Platinum analogues	Carboplatin	Myelosuppression (DLT), nephrotoxicity, nausea/vomiting, electrolyte wasting, hypersensitivity reactions
	Cisplatin	Nephrotoxicity (DLT), nausea/vomiting, ototoxicity, peripheral neuropathy, myelosuppression, electrolyte wasting, diarrhea
Anthracycline	Liposomal doxorubicin	Hand-foot syndrome, mucositis, myelosuppression, discoloration of body fluids, cardiotoxicity
Pyrimidine Antimetabolite	Gemcitabine	Myelosuppression, flu-like symptoms (fever, headache, arthralgias, myalgias), transient skin rash, transient hepatic dysfunction, pneumonitis
Topoisomerase Inhibitor	Topotecan	Myelosuppression (DLT), fatigue
Anti-angiogenesis agent	Bevacizumab	Hypertension, proteinuria, headache, increased risk of thrombosis, surgery and wound healing complications
PARP inhibitors	Olaparib	Fatigue, anemia, nausea
	Niraparib	Fatigue, nausea, thrombocytopenia, neutropenia, elevated liver function tests
	Rucaparib	Nausea, fatigue, anemia, elevations in liver function tests, rash

DLT, dose limiting toxicity; PARP, poly-ADP-ribose polymerase.

Topotecan, an analog of the plant alkaloid 20(S)-camptothecin, is active in patients with metastatic ovarian cancer and is non–cross-resistant with platinum-based chemotherapy.[60] It produces an overall response rate of 21%, with a median time-to-progression of 32 weeks.[61] Topotecan is well-tolerated with minimal nonhematologic toxicities.[61,62] The dose-limiting toxicity is myelosuppression with neutropenia as the most common adverse drug reaction but patients may experience fatigue as well. Patients receiving topotecan have often received multiple other lines of chemotherapy, so they may require dose adjustments or treatment delays for their counts to recover between cycles. For patients unable to tolerate conventional topotecan over 5 days, weekly topotecan on days 1, 8, and 15 of a 28-day cycle may be considered as it has been found to be better tolerated.[63]

Pegylated liposomal doxorubicin is one of the primary agents used for second-line therapy of recurrent ovarian cancer.[64–66] The drug tends to be better tolerated than topotecan, which is important for heavily pretreated patients with advanced disease. The overall response rate with pegylated liposomal doxorubicin is 20%.[65] Median overall survival is longer with pegylated liposomal doxorubicin than topotecan, with a median of 108 weeks versus 71 weeks. Palmar–plantar erythrodysesthesia (PPE) occurs with pegylated liposomal doxorubicin. However, the incidence of PPE in current clinical practice has decreased because the standard dose of pegylated liposomal doxorubicin used currently (40 mg/m^2) is less than the dose that was used in the initial clinical trials and approved by the FDA.[67] Other adverse drug reactions include cardiotoxicity, mucositis, skin rash or hyperpigmentation, and discoloration of urine or body fluids for a day or two following the infusion due to the red color of the drug.

Gemcitabine, a pyrimidine antimetabolite, is also widely used in the treatment of recurrent platinum-resistant ovarian cancer. Although the overall response rate is only about 13% to 22% with single-agent gemcitabine in patients with platinum-refractory recurrent ovarian cancer, an additional 16% to 50% of patients have stable disease for a median of 7 months.[68] The main toxicities include myelosuppression, fatigue, myalgia, and skin rash.

Other agents that have shown an overall response rate of 10% to 25% in patients with recurrent ovarian cancer include etoposide, capecitabine, tamoxifen, letrozole, vinorelbine, and oxaliplatin.[18] Response rates tend to be higher in the platinum-sensitive subgroups. Most of these agents are available in oral formulations, which allows for outpatient administration in the palliative care setting.

The three most commonly used agents in clinical practice are pegylated liposomal doxorubicin, gemcitabine, and topotecan. These agents have demonstrated efficacy when used as a single agent and in combination with other agents. Selection of chemotherapy for treatment of recurrent disease is based on the patient's residual toxicities, scheduling and convenience, and physician preference.

Biologic and Targeted Agents

Although biologic agents as single agents have not demonstrated significant activity for the treatment of ovarian cancer, the results of several clinical trials show that the addition of bevacizumab into first-line and consolidation regimens improves progression-free survival. However, the impact on overall survival is controversial. PARP inhibitors have become a mainstay for ovarian cancer, especially for patients with BRCA mutations, while other targeted therapies, like tyrosine kinase inhibitors, have a limited scope within this malignancy. Though immunotherapy has been found to be effective in many other disease types, ovarian cancer is far more resistant to its effects except in very specific situations like high microsatellite instability.

Anti-Angiogenesis Agents

Bevacizumab is a recombinant humanized monoclonal antibody that targets VEGF, a key mediator of angiogenesis. In the setting of recurrent disease, single-agent bevacizumab produces a response rate similar to other therapies of 16% to 21%.[69,70] Response rates with combinations of bevacizumab range from 15% to 80%.[69–74] However, these phase II trials have also reported a higher risk of bowel perforation in patients treated with bevacizumab-containing regimens.[69,70] Bevacizumab should therefore not be given to patients who have had recent bowel surgery or a history of significant bowel resections. Common adverse drug reactions with bevacizumab include hypertension, proteinuria, and headache, while rare but serious adverse drug reactions include thrombotic events, surgery and wound healing complications, and posterior reversible encephalopathy syndrome. Overall, bevacizumab is typically well-tolerated. In an open-label phase III study (AURELIA Study) that evaluated the combination of bevacizumab in combination with chemotherapy (pegylated liposomal doxorubicin, weekly paclitaxel, or topotecan), the addition of bevacizumab to chemotherapy had no significant impact on overall survival but did improve median progression-free survival (6.4 vs 3.7 months).[75] Based on this study, bevacizumab was approved for use in combination with pegylated liposomal doxorubicin, weekly paclitaxel, or topotecan for treatment of recurrent ovarian cancer.

Recent efforts have focused on the use of bevacizumab in first-line treatment regimens. Although bevacizumab has demonstrated some progression-free survival advantages when used in combination, its effect on overall survival is not clear.[76,77] Furthermore, the benefits do not appear to justify the high cost of bevacizumab (based on pharmacoeconomic studies).[78] As a result, health insurance companies do not consistently reimburse for bevacizumab when used for the primary treatment of ovarian cancer.

Pazopanib, an oral anti-angiogenesis agent, is an alternative treatment regimen for platinum-refractory recurrence.[79] A phase 2 trial assessed oral pazopanib in patients with low-volume recurrent disease who had achieved complete response to initial therapy, with an overall response rate 18%. Single-agent pazopanib is listed as an alternative option for the treatment of platinum-resistant disease in the NCCN guidelines (category 2B recommendation).[18] Adverse drug reactions of pazopanib include diarrhea, hypertension, hair discoloration, hand-foot skin reaction, and a boxed warning for hepatoxicity.

PARP Inhibitors

⑩ PARP plays a critical role in the repair of single-strand DNA breaks via the base-excision repair pathway. Specifically, PARP keeps the low-fidelity nonhomologous-end-joining DNA repair machinery functioning. PARP inhibition results in double-stranded DNA breaks that cannot be repaired in cancer cells with homologous recombinant deficiency, such as those with *BRCA1/2* mutations. Three oral PARP inhibitors are commercially approved for treatment of ovarian cancer—olaparib, rucaparib, and niraparib—with similar FDA-labeled approvals for treatment and maintenance therapy for recurrent ovarian cancer. Both olaparib and niraparib also have FDA-approved indications for "first-line maintenance treatment" after achieving a clinical complete response to platinum-based regimen for ovarian cancers.

In the treatment setting, patients with platinum-sensitive disease have a higher response rate to PARP inhibitors compared to those with platinum-resistant disease (66% vs 20%-30%).[80] However, PARP inhibitors are considered a preferred option in this setting because of the lack of active agents in platinum-resistant disease.[18]

While not commonly discussed, creatinine is a substrate of the MATE 1/2 renal transporter and drug interactions that inhibit or induce the MATE 1/2 pathway will alter serum creatinine levels and ultimately cause a change in CrCl. The class of PARP inhibitors are substrates of and inhibit the MATE 1/2 renal transporter that influences CrCl, so caution is needed in patients with renal insufficiency to monitor for cumulative toxicity.[81] Rucaparib is the only PARP inhibitor with known cytochrome P450 drug interactions involving the 1A2 and 2D6 pathways, so drug interactions must be closely evaluated.[82] The common adverse drug reactions associated with PARP inhibitors include nausea and vomiting and significant anemia with associated fatigue. Patients often require antiemetics and some require transfusion support due to drug-induced anemia. Additional serious but infrequent toxicities include thrombocytopenia, neutropenia, and rarely secondary myelodysplastic syndrome or acute myeloid leukemia. The challenge of combining PARP inhibitors with chemotherapy has been the fatigue, nausea, and significant hematological toxicity, primarily anemia, thrombocytopenia, and neutropenia. The three PARP inhibitors have comparable efficacy and toxicity profiles. Selection of PARP inhibitors will dependent upon patient factors, renal function, and potential drug interactions with concomitant medication.

Other Targeted Agents

Tyrosine kinase inhibitors such as sorafenib and pazopanib inhibit angiogenesis by specifically targeting the VEGF receptor, or VEGFR. When given as single agents, tyrosine kinase inhibitors have demonstrated some antitumor activity in ovarian cancer, but these agents are rarely used due to the toxicity profile. Estrogen receptor antagonists and aromatase inhibitors have also been studied in early phase clinical trials with modest responses.[83] Hormone therapy may be considered in patients who cannot tolerate other regimens or who have not responded to chemotherapy.[18,84]

Immunotherapy

Based on changes in chromosomal instability and epigenetic silencing in ovarian cancer, in theory immunotherapy would be a useful treatment option however studies to date have not demonstrated benefit in ovarian cancer. Improved survival has been correlated with the increased presence of CD3+ tumor-infiltrating lymphocytes and a high CD8+/regulatory T-cell ratio in ovarian cancer patients provides evidence for the immunogenicity of this tumor.[85,86] Increased tumor-infiltrating lymphocytes are linked to tumors with high chromosomal instability such as those with *BRCA* mutation or epigenetic loss. Immunotherapy with pembrolizumab is currently indicated for those with high microsatellite instability, or MSI-H, tumors, which are only seen in 2% of ovarian cancers, or in patients with high tumor mutational burden with at least 10 mutations/megabase and no satisfactory alternative treatment options.[18] Dostarlimab-gxly was also recently approved in patients with solid tumors and no alternative treatment options who have deficient mismatch repair, or dMMR, or high microsatellite instability.[18]

EVALUATION OF THERAPEUTIC OUTCOMES

⑪ During chemotherapy, patients may experience numerous adverse drug reactions such as nausea and vomiting, myelosuppression, neuropathy, and changes in organ function. Patients receiving a taxane or platinum chemotherapy regimen should be monitored for signs of hypersensitivity or infusion-related reactions. Patients treated with paclitaxel often experience infusion-related reactions, which have been attributed to the polyethoxylated castor oil (Cremophor) diluent. Premedications including an H_1-blocker, H_2-blocker, and steroid should be administered prior to each chemotherapy administration to prevent hypersensitivity reactions. If a patient has a reaction, increasing the duration of the infusion from 3 to 6 hours may help with infusion-related reactions. For patients with a true taxane allergy, paclitaxel desensitization can be attempted with 24 hours of premedications (H_1-blocker, H_2-blocker, and steroids) followed by paclitaxel given as a titrated infusion (1:1000 → 1:100 → 1:10 → full dose) over 8 hours. With repeated exposure (ie, seven cycles or more) to carboplatin, patients can develop a delayed hypersensitivity reaction. A similar protocol can be used for carboplatin desensitization.

Ovarian cancer patients receive multiple courses of chemotherapy that can have varying effects on kidney and liver function, often with a delayed onset. Appropriate laboratory tests should be ordered to assess organ function so that chemotherapy doses can be adjusted as indicated. Patients on platinum-containing regimens can often experience electrolyte wasting, so patients should be monitored for electrolyte replacement, IV or oral, as indicated. The use of myeloid growth factors should be considered to prevent treatment delays or dose reductions. Prevention of nausea and vomiting, both acute and delayed, is critical for patients receiving emetogenic chemotherapy regimens.

During initial taxane plus platinum chemotherapy, a CA-125 level should be obtained with each cycle and monitored for at least a 50% reduction in CA-125 after completion of four cycles, which is related to an improved prognosis. Patients who achieve a complete response after completion of first-line treatment should have follow-up once every 3 months, including CA-125, physical examination, pelvic examination, and appropriate diagnostic scans (eg, computed tomography, magnetic resonance imaging, or positron emission tomography), which should be evaluated for presence of disease. In addition to routine follow-up examinations, clinicians should monitor for resolution of any residual chemotherapy-related adverse drug reactions, including neuropathies, nephrotoxicity, ototoxicity, myelosuppression, and nausea and vomiting.

In the progressive disease or recurrent setting, CA-125 levels can be used to monitor for response and should be checked with each cycle, although no change in therapy is recommended until after completion of at least three cycles of the second-line chemotherapy. In addition to laboratory monitoring, appropriate diagnostic scans (eg, computed tomography, magnetic resonance imaging, or positron emission tomography) should be done once every three cycles. Patients need to be monitored with each cycle of chemotherapy to evaluate for new or persistent toxicities such as neuropathies, fluid retention, PPE, myelosuppression, and nausea and vomiting. Another precaution to keep in mind for patients with significant ascites, the "dry weight" or an adjusted body weight should be used for dosing chemotherapy.

Most patients with ovarian cancer will eventually progress through all chemotherapy regimens and investigational treatment options, after which the best supportive care measures should be provided to maintain patient comfort and quality of life. A plan to treat common complications of progressive ovarian cancer, including thrombosis, ascites, uncontrollable pain, and small bowel obstruction, should be developed. This plan should include an opioid-based pain regimen with both long-acting agents and short-acting opioids for breakthrough or progressive pain; it should also include a bowel regimen to prevent opioid-induced constipation. Nausea can be a problem in individuals with advanced ovarian cancer when disease progression causes ascites or partial/complete bowel obstruction. Both antiemetic medications and nonpharmacologic interventions with nutrition and hydration can be helpful. Management of partial or complete small bowel obstruction focuses on controlling symptoms of pain and nausea. Bowel rest with best supportive care may lead to spontaneous resolution of the small bowel obstruction but most often it is a complication associated with rapidly progressive disease. Palliative surgery may be considered for selected patients to relieve symptoms.

ABBREVIATIONS

AUC	area under the curve
BRCA1	breast cancer activator gene 1
BRCA2	breast cancer activator gene 2
CA-125	cancer antigen 125
CrCl	creatinine clearance
FDA	Food and Drug Administration
FIGO	International Federation of Gynecology and Obstetrics
GFR	glomerular filtration rate
GOG	Gynecologic Oncology Group
H_1-blocker	histamine receptor 1 blocker
H_2-blocker	histamine receptor 2 blocker
IP	intraperitoneal
IV	intravenous
NCCN	National Comprehensive Cancer Network
PARP	poly-ADP-ribose polymerase
PPE	palmar–plantar erythrodysesthesia
TAH/BSO	total abdominal hysterectomy/bilateral salpingo-oophorectomy
TVUS	transvaginal ultrasound
VEGF	vascular endothelial growth factor

SELF-ASSESSMENT QUESTIONS

1. SC is a 34-year-old individual that has no children and has a CA-125 of 18 U/mL (kU/L) that presents to the Ovarian Cancer Prevention clinic to be

screened and counseled on risk for developing ovarian cancer. SC's mother died from ovarian cancer at the age of 56 years and older sister has just been diagnosed with ovarian cancer at the age of 42 years. Does SC need to be concerned about developing ovarian cancer too?

A. No, there is hereditary relationship for the risk of developing ovarian cancer.

B. No, SC's CA-125 is within normal range.

C. Yes, individuals with two or more immediate family members with ovarian cancers have an increased risk of developing ovarian cancer.

D. Yes, SC has an elevated CA-125 and could already have cancer.

2. What are the screening recommendations for individual at average risk for the development of ovarian cancer?

A. Annual Papanicolao smear

B. CA-125 level and TVU once every 6 months

C. Annual pelvic exam

D. No screening recommended

3. Which patients should be considered for the addition of neoadjuvant chemotherapy for management of advanced ovarian cancer?

A. All patients

B. *BRCA1/2*+ patients

C. Patients with localized disease

D. Patients presenting with significant tumor burden

4. A patient with *BRCA*-mutated ovarian cancer received adjuvant carboplatin and paclitaxel with a complete response and went on to receive consolidation with olaparib. Unfortunately, 5 months after initial chemotherapy, the patient presents with worsening symptoms and progression shown on CT scans. Which of the following regimens would be appropriate for this patient to receive at this time?

A. Paclitaxel plus cisplatin

B. Paclitaxel plus carboplatin plus bevacizumab

C. Treatment on an investigational study

D. Carboplatin plus gemcitabine plus bevacizumab

5. In a patient with diabetic neuropathy, what chemotherapy regimen would you recommend for primary chemotherapy treatment of ovarian cancer?

A. Paclitaxel 175 mg/m^2 over 3 hours plus carboplatin AUC = 5 over 1 hour

B. Paclitaxel 135 mg/m^2 over 24 hours plus cisplatin 75 mg/m^2 over 4 hours

C. Docetaxel 75 mg/m^2 over 1 hour plus carboplatin AUC = 5 over 1 hour

D. Docetaxel 75 mg/m^2 over 1 hour plus cisplatin 75 mg/m^2 over 4 hours

6. A patient is receiving paclitaxel 175 mg/m^2 IV over 3 hours with carboplatin AUC 5 for primary treatment of ovarian cancer experiences a rare true allergic reaction during the first paclitaxel infusion. Which of the following would be reasonable options to allow completion of the primary chemotherapy treatment?

A. Increase the duration of the paclitaxel infusion time to 6 hours

B. Administer premedications including steroid H_1-blocker and H_2-blocker 24 hours prior to paclitaxel desensitization

C. Discontinue paclitaxel and continue with carboplatin alone for the remaining five cycles

D. Discontinue paclitaxel and replace with topotecan for the remaining five cycles

7. RT is a 27-year-old female that presented with a solid mass on the right ovary. RT underwent TAH/BSO tumor-debulking surgery and was diagnosed with Stage IIA, low-grade ovarian cancer. What adjuvant treatment should RT receive after surgery?

A. Pelvic radiation one-shot

B. Observation with routine 3-month follow-up exams

C. Paclitaxel 175 mg/m^2 over 3 hours plus carboplatin AUC = 5 over 1 hour for six cycles

D. Bevacizumab 15 mg/kg once every 3 weeks for 12 months

8. MP is a 63-year-old female with platinum-sensitive, BRCA1 positive recurrent ovarian cancer that is interested in PARP inhibitor. Which is the most common adverse drug reaction associated with olaparib that would need to be monitored for during therapy?

A. Anemia

B. Thrombocytopenia

C. Constipation

D. Liver dysfunction

9. Which of the following is a common complication of progressive ovarian cancer that may require a surgical intervention for patient comfort?

A. New peritoneal implants

B. Small bowel obstruction

C. Lung nodule

D. Ascites

10. Which of the following would be the most appropriate chemotherapy treatment for patient with recurrent platinum-sensitive cancer?

A. Six cycles of carboplatin plus gemcitabine

B. Six cycles of topotecan plus bevacizumab

C. Six cycles of pegylated liposomal doxorubicin plus bevacizumab

D. Six cycles of paclitaxel plus gemcitabine

11. What supportive medications should be included in the management of ovarian cancer patient with a small bowel obstruction?

A. Ondansetron and oxycodone

B. Loperamide and oxycodone

C. Ondansetron and ibuprofen

D. Loperamide and ibuprofen

12. Which of the following regimens would be most appropriate for the treatment of platinum-resistant recurrent ovarian cancer with a low tumor mutational burden and no identified tumor mutations?

    A. Weekly paclitaxel plus carboplatin

    B. Gemcitabine plus cisplatin

    C. Pembrolizumab

    D. Pegylated liposomal doxorubicin plus bevacizumab

13. Which of the following would improve the activity of olaparib?

    A. Microsatellite instability

    B. HER2 positive disease

    C. BRCA mutation

    D. Lynch syndrome

14. Which of the following is TRUE about ovarian cancer?

    A. It is typically diagnosed at an early stage

    B. Patients often present with nonspecific, vague gastrointestinal symptoms

    C. Patients with advanced disease are often asymptomatic

    D. A common symptom of early disease is bowel obstruction

15. Which of the following is TRUE regarding CA-125 in ovarian cancer?

    A. It is a routine screening test for the detection of ovarian cancer in asymptomatic patients

    B. If within the normal range at diagnosis, changes in levels correlate with tumor burden

    C. Rising levels are often associated with disease progression

    D. In the recurrent setting, levels should be checked every 3 months

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** The risk for ovarian cancer is greater than 50% if there are two or more first-degree relatives with a diagnosis of ovarian cancer or multiple cases of ovarian and breast cancer within the same family. See "Etiology" section in the chapter for more information.

2. **D.** There is no known effective screening method for individuals of average risk of developing ovarian cancer. See "Screening and Prevention" section in the chapter for more information.

3. **D.** In patients with bulky disease, the goal of neoadjuvant chemotherapy is to reduce tumor burden to make surgery more feasible and optimal tumor debulking more likely. See "Neoadjuvant Chemotherapy" section in the chapter for more information.

4. **C.** This patient had recurrence within 6 months of the last platinum therapy, so has platinum-resistant disease. Enrollment in an investigational study is an appropriate regimen for platinum-resistant disease. See "Platinum-Resistant Disease" section in the chapter for more information.

5. **C.** The substitution of docetaxel for paclitaxel does not compromise efficacy and improves tolerability, particularly neurotoxicity in first-line ovarian cancer. Cisplatin also has a higher incidence of peripheral neuropathy than carboplatin, so carboplatin would be preferred as it has similar efficacy and is better tolerated. See "First-Line Chemotherapy" section in the chapter for more information.

6. **B.** Patients with true allergic reactions to paclitaxel can undergo desensitization with 24 hours of premedications prior to administration that is titrated dilutions until at the full rate. See "Evaluation of Therapeutic Outcomes" section in the chapter for more information.

7. **C.** Systemic chemotherapy with a taxane and platinum regimen following optimal surgical debulking is the standard of care for treatment of epithelial ovarian cancer. See the "Treatment" section (First-line Chemotherapy) in the chapter for more information.

8. **A.** The most common adverse drug reactions associated with olaparib include nausea and vomiting and significant anemia with associated fatigue. Thrombocytopenia is most common with niraparib and transient liver toxicity is more often seen with rucaparib. Neutropenia may occur with any PARP inhibitor but is less common. See "Treatment" section (PARP inhibitors) in the chapter for more information.

9. **B.** Common complications of progressive ovarian cancer include thrombosis, ascites, uncontrollable pain, and small bowel obstruction. See "Evaluation of Therapeutic Outcomes" section in the chapter for more information.

10. **D.** See "Table 156-2" for acceptable regimens for recurrent platinum-sensitive ovarian cancer. If the patient is platinum-sensitive, the treatment regimen should contain a platinum agent if patient performance status and comorbidities allow.

11. **A.** Patients with small bowel obstructions should be offered an opioid-based pain regimen with both long-acting agents and short-acting opioids for breakthrough or progressive pain; it should also include a bowel regimen to prevent opioid-induced constipation. Antiemetics are appropriate supportive care as nausea is common with bowel obstructions. See "Evaluation of Therapeutic Outcomes" section in the chapter for more information.

12. **D.** Pegylated liposomal doxorubicin plus bevacizumab would be an appropriate treatment option for platinum-resistant recurrent disease since it is non-cross resistant with platinum agents. Since the patient is platinum-resistant, they should not receive another platinum agent (ie, cisplatin or carboplatin). Immunotherapy with pembrolizumab would be inappropriate since the patient has low tumor mutational burden. See the "Platinum-Resistant Disease" and "Immunotherapy" sections in the chapter for more information.

13. **C.** Olaparib is a PARP inhibitor. PARP inhibition results in double-stranded DNA breaks that cannot be repaired in cancer cells with homologous recombinant deficiency such as those with BRCA1/2 mutations. See "PARP Inhibitors" section in the chapter for more information.

14. **B.** Patients with ovarian cancer often present with nonspecific, vague symptoms such as abdominal bloating, pressure or pain, indigestion, or change in bowel movements. By the time they are diagnosed, the disease is usually advanced leading it to be called "silent killer." Patients with early stage disease are often asymptomatic. See "Clinical Presentation" section in the chapter for more information.

15. C. CA-125 should not be used for routine screening for ovarian cancer for asymptomatic individuals who do not have a high-risk hereditary cancer syndrome. CA-125 is a nonspecific antigen used as a tumor marker for diagnosis and monitoring of epithelial ovarian cancer. Rising levels in those with high baseline levels are associated with disease burden and progression. See "Screening," "Clinical Presentation," and "Evaluation of Therapeutic Outcomes" sections in the chapter for more information.

Chapter 157: Acute Leukemias

David DeRemer; Tara Higgins

KEY CONCEPTS

KEY CONCEPTS

① Acute leukemias are the most common malignancies in children and the leading cause of cancer-related death in patients younger than 20 years.

② Several risk factors correlate with prognosis for acute lymphoblastic leukemia (ALL). Poor prognostic factors include high white blood cell (WBC) count at presentation, very young or very old age at diagnosis, delayed remission induction, and presence of certain cytogenetic abnormalities (eg, Philadelphia chromosome positive [Ph^+]).

③ For children with ALL, remission induction therapy includes vincristine, a corticosteroid, and asparaginase, with or without an anthracycline. For adults with ALL, vincristine, prednisone, anthracycline, and asparaginase are used.

④ All patients with ALL require prophylactic therapy to prevent CNS disease because of the high risk of central nervous system (CNS) relapse. The choice for therapy includes a combination of cranial irradiation, intrathecal chemotherapy, or high-dose systemic chemotherapy with drugs that cross the blood-brain barrier.

⑤ Long-term maintenance therapy for 2 to 3 years is essential to eradicate residual leukemia cells and prolong the duration of remission. Maintenance therapy consists of oral methotrexate and mercaptopurine, with or without monthly pulses of vincristine and a corticosteroid.

⑥ Disease-free survival is lower in adults with ALL and has been attributed to greater drug resistance, poor tolerance with subsequent nonadherence, and possibly less-effective therapy. This population is also more likely to have Ph^+ ALL, which is associated with a worse outcome, but the use of tyrosine kinase inhibitors (TKIs) has improved treatment results.

⑦ Several poor prognostic factors for adult acute myeloid leukemia (AML) include older age, organ impairment, extramedullary disease, and certain cytogenetic and molecular abnormalities.

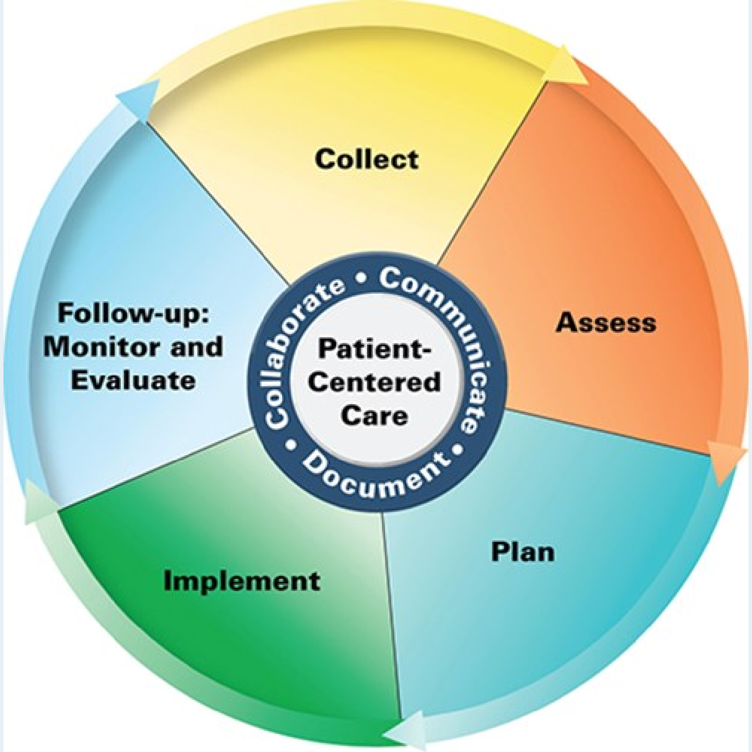
⑧ Treatment of AML usually includes therapy with an anthracycline and cytarabine. Postremission therapy is required in all patients and consists of either consolidation chemotherapy with or without maintenance therapy, or hematopoietic stem cell transplantation (HSCT). Novel oral therapies that inhibit FMS-related tyrosine kinase (FLT-3), isocitrate dehydrogenase (IDH1 and IDH2), and B-cell leukemia/lymphoma (BCL-2) have emerged in the AML treatment landscape.

⑨ Treatment of acute promyelocytic leukemia (APL) consists of induction therapy, consolidation, and maintenance therapy. Induction includes tretinoin and an anthracycline; consolidation therapy consists of two to three cycles of anthracycline-based therapy; maintenance consists of pulse doses of tretinoin, mercaptopurine, and methotrexate for 2 years.

⑩ Hematopoietic growth factors can be safely and effectively used with myelosuppressive chemotherapy for acute leukemias. They reduce the risk of serious infections, hospital length of stay, and treatment delays but do not prolong disease-free or overall survival.

PATIENT CARE PROCESS

Patient Care Process for Ph$^+$ Adult Lymphoblastic Leukemia



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, gender, pregnancy status)
- Patient medical history (personal and family)
- Social history (eg, tobacco/marijuana, ethanol use)
- Current medications including OTCs and herbal products
- Confirmation of histological diagnosis
- Objective data
    - Complete blood count (CBC) with differential, platelets
    - Hepatic function tests
    - Basic chemistry panel
    - DIC panel: D-dimer, fibrinogen, PT, PTT
    - Tumor lysis panel (uric acid, potassium, calcium, phosphate)
    - Hepatitis B/C serologies, HIV, CMV status

  - ABO blood typing
  - Human leukocyte antigen (HLA) typing
- Molecular/cytogenetic information

Assess

- Tumor lysis syndrome risk
- Risk for Hepatitis B reactivation (CD20+ monoclonal antibody)
- Central venous access device
- Echocardiogram or MUGA scan (anthracycline component in ALL therapy)
- Chemotherapy consent (willingness for intrathecal chemotherapy)
- Chemotherapy-induced nausea/vomiting risk
- Hemodynamic stability (eg, systolic blood pressure <90 mm Hg, heart rate >110 bpm, O_2 sat <90%, respiratory rate)
- Presence of active bleeding or bleeding risk factors
- Testicular disease (males)
- Dental evaluation
- Presence of Ph^+ disease
- Emotional status (eg, presence of anxiety, depression)
- Health insurance/prescription drug coverage (eg, hospitalization, BCR-ABL inhibitor)

Plan

- Comprehensive patient education regarding treatment plan
- Drug therapy regimen including multiagent chemotherapy (IV, IT) with corticosteroids and TKI (eg, Hyper-CVAD + rituximab + dasatinib)
- Monitoring parameters including efficacy (eg, circulating blasts, platelets, trilineage hematopoiesis) and safety (eg, signs and symptoms of bleeding, serum creatinine); frequency and timing of follow-up
- Implement supportive care measures (transfusions, hematopoietic growth factors)
- Infection prophylaxis (antifungal, antiviral, *Pneumocystis jirovecii*)
- Referrals to other providers when appropriate
- Initiate donor search for future allogeneic HSCT
- Provide and document discharge summary and patient education

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence with tyrosine kinase inhibitor (ie, dasatinib)

- Schedule clinic follow-up visits

Follow-up: Monitor and Evaluate

- Response assessment (monitor for minimal residual disease [RT-PCR or next generation sequencing to detect BCR-ABL1]) after completion of induction
- PET scans for extramedullary disease if applicable
- Repeat echocardiogram or MUGA scan if applicable
- Physical examination every 1 to 2 months within the first year following completion of therapy
- Referral to Cancer Survivorship clinic

Collaborate with patient, caregivers, and other healthcare professionals.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video "Valerie Shares Her Story for AML Awareness Month" (link – https://www.youtube.com/watch?v=8_CD1Yt1-2k). In this Cancer Care video, patient Valerie shares her journey with AML while she underwent treatment at the MD Anderson Cancer Center. After you watch this video, answer the following questions:

1. What are the signs/symptoms of a newly diagnosed AML patient?
2. What economic challenges does Valerie mention? What are some ongoing initiatives to reduce cancer disparities?
3. Discuss the AML treatment options for induction therapy (pediatric, 18-60, ≥ 60 years old population)
4. When should an AML patient consider a hematopoietic stem cell transplant?

INTRODUCTION

The leukemias are heterogeneous hematologic malignancies characterized by unregulated proliferation of the blood-forming cells in the bone marrow. These immature proliferating leukemia cells (blasts) physically "crowd out" or inhibit normal cellular maturation in bone marrow, resulting in anemia, granulocytopenia, including neutropenia, and thrombocytopenia. Leukemic blasts may also infiltrate various tissues such as lymph nodes, skin, liver, spleen, kidney, testes, and the central nervous system (CNS).

Leukemia is historically classified based on the cell of origin and cell line, and as acute or chronic based on differences in clinical presentation, rapidity of progression of the untreated disease, and response to therapy. The four major leukemias are acute lymphoblastic (or lymphocytic) leukemia (ALL), acute myeloid (or myelogenous) leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myeloid (or myelogenous) leukemia (CML). Undifferentiated immature cells that proliferate autonomously characterize acute leukemias. Chronic leukemias also proliferate autonomously, but the cells are more differentiated and mature. If untreated, acute leukemia is fatal within weeks to months.

EPIDEMIOLOGY

① About 26,710 new cases of acute leukemia—20,050 cases of AML and 6,660 cases of ALL were diagnosed in the United States in 2022, accounting for about 1.5% of the total number of cancers diagnosed. The incidence has been relatively stable for two decades. An estimated 13,100 deaths per year, representing about 2% of all cancer deaths, are caused by acute leukemias.[1]

Leukemia is the leading cause of cancer-related deaths in persons younger than 20 years.[2] It is the leading cause of cancer death for males aged 20 to 39 years, but it is an uncommon cause of cancer-related death for both genders after the age of 40 years. Among adults, acute and chronic leukemias occur at equal rates. More than 90% of the cases of acute and chronic leukemia occur in adults. AML accounts for most cases of acute leukemia in adults and occurs with increasing frequency in older patients.[1]

Despite the low incidence, acute leukemias are the most common malignancy in persons younger than 20 years, accounting for nearly 30% of all childhood malignancies. About 75% of children with leukemia have ALL and most of the remaining cases are AML.[1] Conversely, AML represents about 80% of acute leukemias in adults while only 20% of cases are ALL. Pediatric ALL is about 30% more common in males than in females, peaks at 1 to 4 years of age, and is almost twice as likely to affect Caucasian children than African American children.[2] Geographically, the highest rates of ALL have been identified in the Western portion of the US region.[3] Acute leukemia during the first year of life (infant leukemia) slightly favors ALL over AML.

ETIOLOGY

The exact cause of acute leukemias is unknown. A multifactorial process involving genetics, environmental and socioeconomic factors, toxins, immunologic status, and viral exposures is likely. Infectious and genetic factors have the strongest associations. In pediatric ALL, many environmental factors have been associated with the disease: exposure to ionizing radiation, toxic chemicals, herbicides and pesticides; maternal use of contraceptives, diethylstilbestrol, or cigarettes; parental exposure to drugs, diagnostic radiographs, alcohol consumption, coffee and cola consumption, or chemicals before and during pregnancy; and chemical contamination of groundwater.[4,5] Some studies have reported that high birth weight is a risk factor for ALL. Ionizing radiation and benzene exposure are the only environmental risk factors strongly associated with ALL or AML. Some studies have reported an association between electromagnetic fields of high-voltage power lines and the development of leukemia, but larger studies could not confirm this association. In most patients who develop leukemia, a cause cannot be identified.

PATHOPHYSIOLOGY

Normal hematopoiesis consists of multiple well-orchestrated steps of cellular development. Pluripotent stem cells undergo differentiation, proliferation, and maturation, to form the mature blood cells seen in the peripheral circulation. These pluripotent stem cells initially differentiate into two distinct stem cell pools. The myeloid stem cell gives rise to six types of blood cells (erythrocytes, platelets, monocytes, basophils, neutrophils, and eosinophils). Lymphoid stem cells differentiate into natural killer cells, B-lymphocytes, and T-lymphocytes. Leukemia may develop at any stage and within any cell line.

Two features are common to both AML and ALL. First, both arise from a single leukemic cell that expands and acquires additional mutations, culminating in a monoclonal population of leukemia cells. Second, there is a failure to maintain a relative balance between proliferation and differentiation, so that the cells do not differentiate past a particular stage of hematopoiesis. Cells (lymphoblasts or myeloblasts) then proliferate uncontrollably. Proliferation, differentiation, and apoptosis are under genetic control, and leukemia can occur when the balance between these processes is altered.

AML likely arises from a defect in the pluripotent stem cell or a more committed myeloid precursor, resulting in partial differentiation and proliferation of immature precursors of the myeloid blood-forming cells. In older patients, trilineage leukemia occurs, suggesting that the cell of origin is probably a stem or very early progenitor cell. In younger patients, a more differentiated progenitor becomes malignant, allowing some granulocytic and erythroid populations to mature. These two forms of AML exhibit different patterns of resistance to chemotherapy, with resistance more evident in older adults with AML. ALL is a disease characterized by the proliferation of immature lymphoblasts. In this type of acute leukemia, the defect is probably at the level of the lymphoid stem cell or an early lymphoid precursor.

Leukemic cells have growth and survival advantages over normal cells, leading to a “crowding out” phenomenon in the bone marrow. This growth advantage is not caused by more rapid proliferation than normal cells. It may be caused by factors produced by leukemic cells that either inhibit normal cellular proliferation and differentiation or reduce apoptosis compared with normal blood cells.

Specific genetic alterations that lead to leukemia continue to be elucidated. Genetic defects may include (a) activation of a normally suppressed gene (protooncogene) to create an oncogene that produces a protein product that signals increased proliferation; (b) loss of signals for the blood cell to differentiate; (c) loss of tumor suppressor genes that control normal proliferation; and (d) loss of signals for apoptosis. Most normal cells are programmed to die eventually through apoptosis, but the appropriate programmed signal is often interrupted in cancer cells, leading to continued survival, replication, and drug resistance. Signal transduction, RNA transcription, cell-cycle control factors, cell differentiation, and programmed cell death may all be affected.[6,7]

LEUKEMIA CLASSIFICATION

In 2016, the World Health Organization (WHO) revised the current classification system for myeloid neoplasms (Table 157-1).[8] This classification system incorporates not only morphologic findings, but also genetic, immunophenotypic, cytochemical, and clinical features. With the recent discoveries of mutations involved in AML, the revised classification system expanded the prognostic significance of mutations such as c-KIT, FLT-3, CEBPA, NPM1, IDH, WT1, and TET2 in AML subtypes.

TABLE 157-1

World Health Organization Classification of Acute Myeloid Leukemia and Related Neoplasms

Acute myeloid leukemia (AML) with recurrent genetic abnormalities
AML with t(8;21)(q22;q22.1); RUNX1-RUNX1T1
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22);CBFB-MYH11
APL with PML-RARA
AML with t(9;11)(p21.3;q23.3);MLLT3-KMT2A
AML with t(6;9)(p23;q34.1);DEK-NUP214
AML with inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2); GATA2, MECOM
AML (megakaryoblastic) with t(1;22)(p13.3;q13.3);RBM15-MKL1
AML with BCR-ABL1
AML with biallelic mutations of CEBPA
AML with mutated RUNX1
AML with myelodysplasia-related changes
Therapy-related myeloid neoplasms
AML, not otherwise specified

AML with minimal differentiation
AML without maturation
AML with maturation
Acute myelomonocytic leukemia
Acute monoblastic/monocytic leukemia
Pure erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Transient abnormal myelopoiesis
Myeloid leukemia associated with Down syndrome

PML, promyelocytic leukemia, RARα, retinoic acid receptor-α.

ALL is classified based on lymphoblast analysis. Immunophenotype is determined by flow cytometry that analyzes specific antigens, known as clusters of differentiation (often abbreviated "CD"), present on the cell surface. Although no leukemia-specific antigens have been identified, the pattern of cell-surface antigen expression reliably distinguishes between lymphoid and myeloid leukemia. The immunophenotype defines the cell of origin. The major phenotypes are mature B-cell, precursor B-cell, and T-cell disease, but the WHO classifies ALL as either B lymphoblastic or T lymphoblastic. About 80% of childhood ALL derives from precursor B cells and about 15% from T cells; the remainder is from mixed lineage or mature B cells. T-cell ALL is more common in teenage males. In adults, about 75% of ALL is B-cell lineage and 25% is T-cell lineage ALL.

Leukemias may also be described by cytogenetic abnormalities. Chromosome alterations include numerical (hyperdiploidy and hypodiploidy) and structural abnormalities due to exchanges of genetic information within (inversion) or between (translocation) chromosomes. Unique translocations can identify specific subtypes of acute leukemia. The most common translocation in adult ALL, occurring in 25% of patients, is the t(9;22) or Philadelphia chromosome positive (Ph^+), which causes fusion of the BCR signaling protein to the ABL nonreceptor tyrosine kinase, resulting in constitutive tyrosine kinase activity. Acute promyelocytic leukemia (APL) is characterized by a specific translocation between chromosomes 15 and 17: t(15;17). Molecular tests may be used to identify products of specific translocations, such as promyelocytic leukemia (PML) retinoic acid receptor-α (RARα) in APL and *AML1-ETO* and *CBFβ/MYH 11* in other subtypes of AML.

Several factors can affect the cytogenetics of AML in adults. First, in about 5% of patients, simultaneous blood and marrow samples demonstrate normal cytogenetics versus abnormal cytogenetics, respectively. Second, central cytogenetic analysis is done in multicenter trials because of variability in specimen examination. Some patients have a normal karyotype on standard review, but carry fusion genes, which are identical to those of translocations or inversions.[8] These insertions of very small chromosome segments do not alter chromosome morphology but may affect outcome.

CLINICAL PRESENTATION

At presentation, common signs and symptoms result from malignant cells that replace and suppress normal hematopoietic progenitor cells and infiltrate into extramedullary spaces. Patients with acute leukemia often present with symptoms related to complications of pancytopenia (eg, anemia, neutropenia, and thrombocytopenia) which include fatigue, infections, gingival bleeding, ecchymoses, and epistaxis.

In addition to clinical presentation, laboratory and pathology evaluations are required for a definitive diagnosis of leukemia. An abnormal complete blood count (CBC) is usually the diagnostic test that initiates a leukemia workup. Although leukemic blast cells may be present on the peripheral blood smear, they are not diagnostic of leukemia because there are other explanations for why immature blast cells may be present in peripheral blood. The most important diagnostic test is a bone marrow biopsy and aspirate, which is submitted to hematopathology for numerous evaluations, including flow cytometry, cytogenetics, and immunophenotyping. A lumbar puncture is performed to determine if there are blasts in the CNS. Unlike ALL, AML is less commonly associated with CNS involvement. A chest radiograph or computed tomography is performed to screen for a mediastinal mass (most common in T-cell disease). The results of these evaluations help to determine the patient's prognosis and therapeutic plan.[9]

CLINICAL PRESENTATION: Acute Leukemias

General

- Recent history of vague symptoms such as tiredness, lack of exercise tolerance, weight loss, and "feeling unwell," but in no obvious distress.

Signs and Symptoms

- Common: Patients with anemia present with pallor, malaise, palpitations, and fatigue. Patients with low platelet count present with bruising, ecchymoses, and petechiae. Temperature is often elevated and may be caused by disease or infection. Patients may have bone pain from hyperactive bone marrow.
- Other possible symptoms include epistaxis, dyspnea on exertion, seizures, or headache. Splenomegaly, hepatomegaly, or lymphadenopathy are common in patients presenting with ALL, but painless testicular enlargement and rarely, small, blue-green collections of leukemia cells under the skin (chloromas) may also be present. Patients with AML may present with gum hypertrophy and bleeding.

Laboratory Tests

- Complete blood count with differential. Anemia (<7 g/dL [70 g/L; 4.34 mmol/L]) is normochromic and normocytic (without a compensatory increase in reticulocytes). Thrombocytopenia (severe, <20,000 cells/mm^3 [20 × 10^9/L]) is present in 28% of ALL and 50% of AML cases. Patients can present with leukopenia or leukocytosis; about 20% of patients will present with a WBC count ≥50,000 cells/mm^3 (50 × 10^9/L) and 53% of ALL and 20% of AML cases with a WBC <10,000 cells/mm^3 (10 × 10^9/L). Even patients with elevated counts can be considered functionally neutropenic.
- Uric acid may be elevated because of rapid cell turnover and is more common in patients presenting with elevated WBC count and with ALL.
- Electrolytes: potassium and phosphate may be elevated with a compensatory decrease in calcium, more common with ALL.
- Coagulation (more common with AML): elevated prothrombin time, partial thromboplastin time, D-dimers; hypofibrinogenemia.

Other Diagnostic Tests

- Bone marrow aspirate and biopsy: send for morphologic examination, cytochemical staining, immunophenotyping, and cytogenetic (chromosome) analysis. Molecular testing for FMS-like tyrosine kinase 3 (FLT3), nucleophosmin (NPM1), and CCAAT/enhancer binding-protein α (CEBPA), mutations is warranted for suspected AML.
- All adults with ALL should have a screening lumbar puncture performed to assess CNS involvement. Screening in patients with AML is not routine and depends on multiple factors at presentation including symptoms, WBC count, and morphology that includes monocytic disease.
- All pediatric patients with acute leukemias will receive a diagnostic lumbar puncture and intrathecal chemotherapy at that time (intrathecal is usually performed on day 1 of induction chemotherapy for ALL and within the first week of induction for AML patents).

ACUTE LYMPHOBLASTIC LEUKEMIA

Risk Classification

② Several clinical and biological features at diagnosis are associated with response to treatment, as measured by the complete remission rate, duration of remission, and long-term survival. The patient's response to initial therapy is strongly associated with response to treatment. Identifying these risk factors allows the clinician to better understand the disease and personalize treatment according to the risk of disease recurrence (ie, risk-adapted therapy). For example, if a patient has many clinical and laboratory features that are associated with a favorable response to antineoplastic therapy (standard risk), the clinician may give less-intensive therapy to reduce the risk of long-term adverse effects. Conversely, if a patient is unlikely to respond well to standard therapy (high-risk or very-high-risk disease), the clinician may give more intensive antineoplastic therapy. The factors can be grouped as follows: patient characteristics at diagnosis, leukemic cell features at diagnosis, and patient response to initial therapy.

The National Cancer Institute (NCI) developed an ALL-risk stratification to create a standard for comparison in children.[10] Induction therapy is initially selected based on this classification, which divides children into standard- or high-risk categories based on age and initial WBC count (Table 157-2a). Age remains an independent predictor of outcome with children aged 1 to 9 years having the best event-free survival, possibly due to a more frequent favorable cytogenetics in this age group.[11] Age and WBC count has limited prognostic importance in T-cell ALL.[10] The presence of CNS disease at diagnosis is associated with a higher relapse rate. About 2% of males have testicular disease at diagnosis, but not all cooperative groups classify this as an adverse prognostic factor. Male ALL patients have a slightly worse prognosis.[12]

TABLE 157-2a

National Cancer Institute (NCI) Risk Classification for Pediatric Acute Lymphoblastic Leukemia

Risk Group	Standard Risk	High Risk
Age (years)	1– <10	<1 or ≥10
WBC count (× 10^3 cells/mm^3 or × 10^9/L)	<50	≥50
Karyotype	No t(9;22) or t(4;11)	t(9;22) or t(4;11)

WBC, white blood cell.

Data from Smith M, Arthur D, Camitta B, et al. Uniform approach to risk classification and treatment assignment for children with acute lymphoblastic leukemia. J Clin Oncol. 1996;14:18-24.

Cell surface and immunophenotype classify childhood ALL into B-cell (85%) or T-cell (15%). T-cell ALL patients are often male, African American, older, and less likely to be Hispanic than B-cell ALL. T-cell ALL generally presents with higher WBC counts and has mediastinal lymph node and CNS involvement. Historically, survival for T-cell ALL was inferior to B-cell ALL, but this difference has narrowed with more intensive therapy.[10] Several cytogenetic abnormalities are associated with prognosis. Favorable outcomes are associated with the presence of trisomy of chromosomes 4 and 10, high hyperdiploidy (chromosome number >50 and DNA index >1.16), and the *ETV6-RUNX1* cryptic translocation, t(12;21).[13] Unfavorable or poor prognostic genetic factors are hypodiploidy (chromosome number <44), MLL rearrangement, BCR-ABL1, Ph-like ALL, CRLF2 rearrangement, intrachromosomal amplification of chromosome 21, and IKZF1 alterations (common in Ph-positive and Ph-like ALL).[10] Ph-like ALL can have translocations similar to BCR/ABL (ie, fusions including ABL1 [non-BCR], ABL2, CSF1R, and PDGFRB) or defects in the Janus kinase (JAK) pathway. The most common cytogenetic abnormalities in B-cell ALL are hyperdiploidy (25%), ETV6-RUNX1 (25%), MLL (5%), hypodiploidy (1%-5%), and Ph-positive (4%).[13]

The strongest prognostic factor for ALL is response to therapy. Previous predictors for early response to treatment were response to the first week of glucocorticoid therapy and evaluation of marrow blasts following 1 to 2 weeks of induction therapy. Minimal residual disease (MRD) quantification at the end of induction has become the most important prognostic factor. Molecular measurement of subclinical MRD by either flow cytometry or polymerase chain reaction detects leukemic cells not visible on morphologic examination to assess treatment response and detect relapse. This technique detects one leukemia cell per 10^4 to 10^5 normal cells. The goal is to have MRD less than 0.01% at the end of remission induction therapy. Children with higher levels have a 3 to 5 times greater risk of treatment failure and death.[10]

The Children's Oncology Group uses a risk- and response-based classification of childhood ALL (Fig. 157-1). This classification system uses the NCI-risk assignment to initially categorize patients into standard- or high-risk groups (see Table 157-2a). Following induction therapy, the risk is reclassified based on completeness of response to therapy, the presence or absence of cytogenetic abnormalities, and CNS involvement (Table 157-2b). Patients are then reclassified as low risk, standard risk, high risk, or very-high risk (see Fig. 157-1). Patients who initially high risk do not have their therapy reduced, but may have it intensified to very high risk.

Note: See Table 157-2a for criteria used to categorize patients into initial risk categories.

Data from Schultz KR, Pullen DJ, Sather HN, et al. Blood. 2007;109:926-935.

Children are classified as low risk and will have therapy reduced if they have trisomy 4 and 10 or the *ETV6-RUNX1* cryptic translocation with less than 0.01% MRD on day 29 bone marrow samples and do not have CNS or testicular disease. Children with testicular disease, MRD greater than or equal to 0.01% on day 29, or who received steroids before diagnosis have postinduction therapy intensified and are classified as high risk. Childhood precursor B-ALL with more than five WBCs and blasts present in the cerebrospinal fluid (CSF), Ph^+ disease, hypodiploidy, $iAMP_{21}$, induction failure, or *MLL* gene rearrangement have therapy intensified and are considered very high risk. Infant ALL, trisomy 21, or childhood T-cell ALL have unique risk classification schemas.[13] Relapse occurs in 15% to 20% of children with ALL. Factors associated with prognosis include time to relapse (ie, shorter time), immunophenotype (ie, T cell), and site of relapse (ie, bone marrow disease). If relapse occurs following the completion of primary treatment, the likelihood of cure is about 50%. If a patient relapses during therapy, only 20% to 30% are cured.[10]

Treatment—Acute Lymphoblastic Leukemia

Desired Outcomes

The short-term goal for ALL treatment is to rapidly achieve a complete clinical and hematologic remission (CR), defined as the disappearance of all physical and bone marrow evidence (normal cellularity with less than 5% blasts) of leukemia, with restoration of normal hematopoiesis. After a CR is achieved, the goal is to maintain the patient in continuous CR. A child is generally considered cured after being in continuous CR for five years.

Successful treatment of ALL was first developed in children. Cure rates in children have risen from less than 10% with treatments used in the 1960s to current rates of about 90%.[10] The reason for this improvement lies primarily in improved scheduling of existing drugs, as relatively few new drugs have come to the market since the 1960s. MRD is a strong predictor of relapse in ALL. Children with low-risk disease have a 5-year event-free survival of more than 95%. The 5-year event-free survival for average-risk disease is 90% to 95%. The 5-year event-free survival is nearly 90% for high-risk childhood B-precursor and T-cell ALL. Children with very-high-risk disease have a 5-year event-free survival of less than 80%.[14] Response to treatment is determined by intrinsic drug sensitivity and the patient's pharmacogenomics and pharmacodynamics, treatment received, and treatment adherence.

Although treatment response with adult ALL is worse than those with childhood ALL, recent use of aggressive chemotherapy in adult ALL has increased the initial CR rate after induction therapy from 60% to 85%. Long-term event-free survival in this population, however, remains low (between 30% and 40%) because a higher proportion of adults present with high-risk disease. CR rates and event-free survival depend on several poor prognostic factors and certain types of ALL are associated with a very poor outcome.

Treatment Phases

Therapy for childhood ALL is divided into five or six phases: (a) induction, (b) consolidation therapy, (c) interim maintenance, (d) delayed intensification, (e) interim maintenance II, and (f) maintenance therapy (Fig. 157-2). CNS prophylaxis is a mandatory component of ALL treatment regimens and is administered longitudinally during all phases of treatment. The total duration of treatment is 2 to 3 years.[13,15]

Induction

③ The goal of induction is to rapidly induce a CR. The CR rate is about 98% for standard-risk children treated with vincristine, a glucocorticoid (dexamethasone or prednisone), and pegaspargase.[10] Many treatment protocols include daunorubicin in induction (four-drug induction) for high-risk or very-high-risk ALL. Most children achieve a CR in 4 weeks. Those who have positive MRD at day 29 receive intensified therapy. About 2% to 3% of children fail induction therapy and have a 10-year survival rate of 32%.

Prednisone has been the primary glucocorticoid used in pediatric ALL regimens but has been replaced with dexamethasone in most standard-risk protocols due to its longer duration of action and higher CSF penetration.[16] Dexamethasone improves event-free survival and decreases the risk of CNS relapse, but increases the risk of osteonecrosis, mood alteration, steroid myopathy, hyperglycemia, and infections.[16,17] Adolescents (older than 10 years) are particularly prone to osteonecrosis and receive prednisone instead of dexamethasone to minimize this adverse drug reaction.[12] Patients with Down syndrome also receive prednisone because they have increased infections and mortality with dexamethasone.[18]

Asparaginase has historically been available in three forms. L-Asparaginase (no longer manufactured in the United States) and pegaspargase are isolated from *Escherichia coli,* while Erwinia asparaginase is isolated from *Erwinia chrysanthemi*. Erwinia asparaginase is generally utilized in the setting of an allergic reaction to *E. coli* asparaginase. Erwinia asparaginase is given intramuscularly or intravenously. Erwinia asparaginase intravenously may require more frequent administration every 48 hours or the need for nadir serum asparaginase activity if every 72 hour dosing is required (ie, Monday, Wednesday, and Friday administration).[19] Asparaginase erwinia chrysanthemi (recombinant)-rywn is a new asparaginase product on the market. The dose is vastly different from Erwinia asparaginase.[20] An additional novel asparaginase product calaspargase pegol-mknl has also been developed.[21] Pegaspargase is pegylated *E. coli* asparaginase; pegylation prolongs its duration of activity and allows it to be given less frequently. Pegaspargase is used in most protocols and is preferred over L-asparaginase because of fewer intramuscular injections, decreased antibody formation, and superior response rates. Pegaspargase is also approved for IV administration.[22] The addition of asparaginase and an anthracycline to vincristine and prednisone improves remission rates from 85% to 95%.[15]

Asparaginase products are the antineoplastic agents used in ALL which are most likely to cause hypersensitivity reactions. Depending on the type of asparaginase used and the presence of a co-administered steroid, 8% to 42% of patients may develop hypersensitivity reactions to asparaginase.[23] Hypersensitivity reactions to pegaspargase may have a delayed onset (when administered intramuscularly) and prolonged duration, sometimes requiring hospitalization.[24] *Erwinia* asparaginase is only used for patients who are allergic to pegaspargase. Because *Erwinia* asparaginase has a short half-life, it must be administered more frequently. A single dose of pegaspargase is replaced by six doses of *Erwinia* asparaginase, given three times per week.[25]

Patients may develop silent inactivation, also known as subclinical hypersensitivity, in which they develop neutralizing antibodies that can rapidly inactivate asparaginase, but without developing a clinical hypersensitivity reaction. Silent inactivation can be detected by therapeutic monitoring of asparaginase activity. If inadequate asparaginase activity is detected, a therapeutic switch from pegaspargase to *Erwinia* asparaginase can be made to optimize activity and outcomes. The use of therapeutic drug monitoring to optimize the dosing of asparaginase has also been demonstrated in clinical trials.[26]

Central Nervous System Prophylaxis

④ Central nervous system prophylaxis is incorporated throughout all phases of therapy. The rationale for CNS prophylaxis is based on two observations. First, many antineoplastic agents do not readily cross the blood-brain barrier. Second, results from early clinical trials showed that most patients with ALL experienced CNS relapse.[10] These observations indicate that the CNS is a potential sanctuary for leukemic cells and undetectable leukemic cells are present in the CNS in many patients at the time of diagnosis, while only 3% of children have detectable CNS involvement at diagnosis.[11]

The goal of CNS prophylaxis is to eradicate undetectable leukemic cells from the CNS while minimizing neurotoxicity and late effects. Once CNS relapse has occurred, patients are at increased risk of bone marrow relapse and death from refractory leukemia. Initial trials of childhood ALL in the 1960s established craniospinal irradiation as the standard for prevention of CNS relapse. However, this approach is associated with long-term sequelae including neuropsychological deficits, precocious puberty, osteoporosis, decreased intellect, thyroid dysfunction, brain tumors, short stature, and obesity. Subsequent trials showed that irradiation may be replaced by frequent administration of intrathecal chemotherapy in children with ALL. Some centers may treat children with CNS disease at diagnosis or very-high-risk disease with cranial radiation. The use of CNS irradiation and early intensified intrathecal chemotherapy has decreased the rate of CNS relapse to less than 5%.[12]

The CNS prophylaxis regimen is selected based on efficacy, toxicity, and risk of CNS disease. Intrathecal chemotherapy, cranial irradiation, dexamethasone, and high-dose IV methotrexate or cytarabine can be used to treat or prevent CNS disease. At least 80% of children with newly diagnosed ALL are treated without cranial radiation.[10] Risk factors for CNS relapse include male sex, hepatomegaly, T-cell phenotype, CNS2 disease (the presence of leukemic blasts in a CSF sample that contains less than 5 WBC/mm^3 [5×10^6/L]), age younger than 2 years or older than 6 years, and a bloody diagnostic lumbar puncture.[14,27] Intrathecal therapy consists of methotrexate and cytarabine, given either alone or in combination. When given together, hydrocortisone is commonly added (triple intrathecal therapy) to decrease the incidence of arachnoiditis. Triple intrathecal therapy is typically reserved for children with refractory CNS disease. For standard-risk ALL, triple intrathecal therapy decreased CNS relapse rates by 30% as compared to intrathecal methotrexate but had no effect on event-free survival and worsened overall survival.[27] Liposomal cytarabine given intrathecally can induce remission of CNS disease but is associated with arachnoiditis and other CNS-related adverse effects.[28]

Patients with T-cell leukemia have an increased incidence of CNS disease and usually receive systemic therapy that penetrates the CNS such as high-dose methotrexate. Patients with T-cell disease have lower methotrexate polyglutamate accumulation in leukemic blasts and therefore were expected to require higher doses of methotrexate intravenously. The Capizzi methotrexate regimen, which consists of low escalating doses of methotrexate without leucovorin rescue plus pegaspargase, was superior to high-dose methotrexate with leucovorin rescue in 90% of patients receiving cranial radiation therapy.[29]

Consolidation Therapy

Consolidation therapy is initiated after a CR has been achieved and refers to continued intensive antineoplastic therapy to eradicate clinically undetectable disease to secure (consolidate) the remission. Regimens usually incorporate either non–cross-resistant drugs that are different from the induction regimen, or more dose-intensive use of the same drugs.

Randomized trials show that consolidation therapy improves patient outcomes in children, but its benefit in adults is less clear. The relative benefit of individual components of treatment regimens is difficult to demonstrate because of the overall complexity of therapy in ALL. Standard consolidation lasts 4 weeks and usually consists of vincristine, mercaptopurine, and intrathecal methotrexate. In children, the intensity of consolidation therapy is personalized based on the child's initial risk classification and response to induction therapy. Children with high-risk disease receive intensified consolidation that includes the addition of pegaspargase, cyclophosphamide, and low-dose cytarabine to standard therapy.[10,13] Children with testicular disease usually receive radiation during this phase of therapy if a complete clinical response in the testes is not achieved by the end of induction. Patients with T-cell leukemia also receive nelarabine, a prodrug of ara-G that preferentially accumulates in T-lymphoblasts as ara-guanosine triphosphate (GTP), during consolidation and throughout the remainder of their treatment course because it improves event-free survival when it is added to an intensified-therapeutic backbone.[30]

Reinduction (Interim Maintenance and Delayed Intensification)

One or two interim maintenance phases separated by a high-intensity delayed intensification cycle can be added to maintain remission and decrease cumulative toxicity (Fig. 157-2). Interim maintenance is given to all ALL patients. Standard-risk patients receive one interim maintenance cycle that includes IV methotrexate (low dose that escalates over the course of the cycle) and vincristine while high-risk patients receive interim maintenance which includes vincristine, high-dose methotrexate, and mercaptopurine. High-risk patients receive a second interim maintenance after delayed intensification which is similar to standard-risk interim maintenance but adds asparaginase. Delayed intensification is similar for both standard- and high-risk patients and includes vincristine, glucocorticoid, doxorubicin, asparaginase, cyclophosphamide, cytarabine, and thioguanine.[11,12,15] ALL patients previously received one interim maintenance and two delayed intensification cycles. Delayed intensification with dose intensification improved event-free survival and decreased late relapses for high-risk childhood ALL, but there was no additional benefit for the second delayed intensification cycle. Children on the intensified arms of the study received significantly more antimicrobial drugs, blood products, and parenteral nutrition but had no increase in treatment-related mortality.[31] These phases use an augmented schedule and chemotherapy dose that reduces tumor burden and prevents the emergence of drug resistant clones.[12]

Maintenance Therapy

5 Maintenance therapy provides long-term drug exposure to slowly dividing cells, allows the immune system time to eradicate leukemia cells, and promotes apoptosis (programmed cell death). The goal of maintenance therapy is to further eradicate residual leukemic cells and prolong remission duration. Although maintenance therapy is clearly beneficial in childhood ALL, the benefit in adults has only been demonstrated.

Maintenance therapy usually consists of daily mercaptopurine and weekly methotrexate for 12-week courses, at doses that produce mild myelosuppression, with monthly pulses of vincristine and a steroid.[10,31] Since male children treated for 2 years versus 3 years have a slightly higher risk of late relapse (excluding isolated testicular relapse), some centers treat female children for 2 years while males receive maintenance for a total of 3 years of therapy.[11] The most recent Children's Oncology Group trial requires 2 years of therapy for male and female children.

Mercaptopurine and oral methotrexate are available as tablets and as an FDA-approved commercially available oral suspension. It was previously recommended that mercaptopurine be taken at night and administered on an empty stomach without concomitant milk products. It was thought xanthine oxidase in milk products would inactivate the drug and circadian rhythm would affect absorption. However, red cell thioguanine levels are not influenced by coadministration of food or dairy, timing of administration or whether the tablet is swallowed whole, crushed, or chewed. Therefore, previous recommendations may hinder drug adherence.[32] Interpatient variability in the adherence and systemic exposure to oral methotrexate and mercaptopurine is an important determinant of the effectiveness and toxicity of maintenance therapy. Children with an adherence rate less than 95% with mercaptopurine have a 2.7-fold higher risk of suffering a relapse.[33] Factors associated with nonadherence include single-parent household, adolescence, lower socioeconomic status, and Hispanic ethnicity.[34] To account for the interpatient variability, most clinicians will titrate the dose of these agents to achieve adequate myelosuppression.[11] Some clinicians overcome variable bioavailability and poor adherence issues by administering methotrexate IV or intramuscularly. The importance of these pharmacokinetic issues in adults is not well defined.

Genetic polymorphisms may affect drug metabolism, receptor expression, drug transport, drug disposition, and pharmacologic response. Pharmacogenomic polymorphisms are an important determinant of mercaptopurine toxicity. Thiopurine methyltransferase (TPMT) is the predominant inactivating enzyme for thiopurines in hematopoietic tissues. About 10% of the population has intermediate TPMT activity because of heterozygous polymorphisms in the gene encoding for TPMT, and 1 in 300 has extremely low activity because of homozygous presence of this TPMT polymorphism. Patients with low activity (homozygous mutant TPMT genotype) require a tenfold dose reduction and frequency change to three times weekly instead of daily. Heterozygous or intermediate metabolizers will require an initial dose reduction of 30% to 80% if the dose is 75 mg/m^2/day or greater. If the mercaptopurine dose is less than 75 mg/m^2/day, then dose reduction may not be recommended.[35] TPMT testing is now a standard of care at many institutions and treatment dosing is adjusted to minimize toxicity without compromising anti-leukemic outcomes. A coding variant in nudix hydrolase 15 (NUDT15) is another important determinant of thiopurine toxicity. NUDT15 encodes a nucleoside diphosphatase that dephosphorylates active thiopurine metabolites, which prevents them from incorporating into DNA and minimizes their cytotoxicity. If a patient has defective NUDT15 alleles, active thiopurine metabolites can accumulate and cause toxicity.[36]

Philadelphia Chromosome Positive Acute Lymphoblastic Leukemia

Ph$^+$ ALL has historically been treated as very-high-risk disease, which includes the use of a four-drug induction regimen with continuous imatinib mesylate, a tyrosine kinase inhibitor (TKI) that inhibits BCR-ABL kinase, throughout all phases of treatment. This targeted therapeutic approach results in a 5-year overall survival of 70%. The results for patients receiving chemotherapy with imatinib were similar to those receiving hematopoietic stem cell transplantation (HSCT).[37] Imatinib is incorporated into childhood treatment trials for Ph$^+$ ALL in Europe and the United States. Dasatinib shows improved event-free and overall survival compared to imatinib-treated patients with pediatric Ph$^+$ ALL.[38,39] Ph-like ALL is more common in the adolescent and young adult age group (ie, 15-39 years). TKIs (dasatinib), JAK inhibitor (ruxolitinib), and mTOR inhibitors (sirolimus and everolimus) are being investigated for Ph-like ALL.[12,15]

Acute Lymphoblastic Leukemia in Adolescents and Young Adults

Although ALL is relatively uncommon in adolescents and young adults (15-39 years old [AYA]), the outcomes are generally worse than for childhood ALL.[13] The number of AYA patients with ALL has doubled since 1975 and it is estimated to be about 1,200 new diagnoses per year since 2006. In the last decade, about 50% of AYA patients with ALL survived 10 years. ALL in AYA has a higher frequency of T-cell immunophenotype and a lower frequency of the t(12;21)(p13;q22) cryptic translocation responsible for hyperdiploidy and the *ETV6-RUNX1* fusion gene; and increased incidence of Ph$^+$ ALL, intrachromosomal amplification of chromosome 21, and Ph-like ALL which occurs most frequently in the AYA population. Thirteen studies have compared outcomes of AYA patients treated with either pediatric or adult regimens. Pediatric-inspired regimens had better outcomes reported in 12 of the 13 studies. Event-free survival rates ranged from 60% to 77% with pediatric regimens versus 32% to 72% with adult regimens, with an overall survival rate of 27% to 80% versus 10% to 74% for pediatric and adult regimens, respectively. Treatment outcomes for AYA patients undergoing related or unrelated HSCT were compared to similar patients treated with pediatric chemotherapy regimens. Patients treated with chemotherapy alone had a similar relapse rate but significantly less treatment-related mortality. The AYA patients treated with chemotherapy had a significantly higher 4-year survival rate.

The toxicity of chemotherapy regimens is a vital consideration when treating the AYA population. Pediatric regimens do not usually require hospitalization and have a low potential for cardiotoxicity, infertility, and carcinogenesis while adult regimens often require hospitalization for neutropenic fever and other infectious complications. Pediatric chemotherapy regimens are associated with an overall increase in both life years and quality-adjusted life years (QALYs) following the initial stages of treatment. Based on mental health and quality-of-life surveys, depression, anxiety, and posttraumatic stress disorder were present in one-third of AYA patients. Adherence is more problematic in the AYA population due to education, employment, various relationships, and insurance. Oral chemotherapy agents are a large portion of treatment in pediatric regimens while adult regimens often require inpatient therapy, thus affecting school or employment. Both require reliable access to transportation.[40]

Acute Lymphoblastic Leukemia in Adults

⑥ Risk stratification for adult patients depends on age and Philadelphia chromosome status. The National Comprehensive Cancer Network (NCCN) guidelines recommend different strategies for AYA (15-39 years), adults (40-65 years), and older adults (≥65 years) with substantial comorbidities.[41] The most common treatment regimens use a four-drug induction regimen consisting of an anthracycline, vincristine, an asparaginase, and a corticosteroid. These regimens produce high CR rates (>70%), but the long-term event-free survival is unsatisfactory.[42] Poorer outcomes in adults have been attributed to differences in cytogenetic abnormalities, greater drug resistance, higher risk of treatment-related adverse drug reactions with subsequent nonadherence, and possibly less-effective therapy. Several different regimens are considered appropriate first-line therapies in adults including the Cancer and Leukemia Group B (CALGB) 8811 (Larson regimen), Eastern Cooperative Oncology Group (ECOG) 2903, or Linker regimen.[41] Some studies suggest that high-dose methotrexate and cytarabine alternating with fractionated cyclophosphamide plus vincristine, doxorubicin, and dexamethasone (hyper-CVAD) may improve response and survival in adults with ALL. Many cases occur in patients older than 65 years, and the response to therapy and durability of response in this subgroup is less than in other populations. Treatment-related mortality rates during remission induction therapy are also higher in this population.[42]

While the overall incidence of Ph^+ disease is 25% in adults, the incidence rises to over 40% in adults older than 50 years. Historically, patients with Ph^+ ALL had a poor prognosis, with 1-year survival of about 10% without an allogeneic HSCT.[42] As compared with historical control patients treated with standard chemotherapy alone, the addition of BCR-ABL TKI-based therapy to chemotherapy is associated with an increased CR rate and overall survival.[43–46] TKIs should be incorporated early in the Ph^+ ALL patient and continuous dosing has demonstrated superior outcomes compared to pulse or intermittent dosing strategies. For patients older than 65 years or those with poor performance status, remission induction regimens may include a BCR-ABL TKI (imatinib, dasatinib, bosutinib, or nilotinib) combined with corticosteroids.[41]

The emergence of resistance to BCR-ABL TKIs provides a challenge in patients relapsing after treatment. Point mutations within the ABL kinase domain and the activation of alternative signaling pathways due to SRC kinase have been identified. A patient's specific mutation analysis should be considered when a specific TKI is selected in the relapsed or refractory setting. Second- and third-generation TKIs have demonstrated activity in patients with imatinib-resistant Ph^+ ALL, but ABL mutations such as T315I, V299L, and F317L have demonstrated resistance to dasatinib. Ponatinib is the only BCR-ABL TKI available with known activity against T315I mutations. With the emergence of more potent inhibitors that can induce sustained remissions, studies evaluating the need for intensive chemotherapy are ongoing.[47]

In adults with B-cell ALL, about 50% have leukemic cells that express CD20. CD20 expression is associated with decreased CR rates, higher risk of relapse, and shorter overall survival.[48] The addition of rituximab to hyper-CVAD results in a higher CR rate (70% vs 38%) and longer overall survival (75% vs 47%) as compared with hyper-CVAD alone.[49] Ofatumumab, a more potent second-generation anti-CD20 monoclonal antibody, was also added to hyper-CVAD and produced CR and MRD negativity rates of 98% and 93%, respectively.[50]

HSCT plays an important role in the treatment of adult patients with ALL. For patients with ALL who have a CR after induction therapy, consolidation with allogeneic HSCT should be considered if a human leukocyte antigen (HLA)-matched sibling or matched unrelated donor is available. After HSCT, patients with Ph^+ ALL should continue with standard maintenance therapy that includes a TKI. Allogeneic HSCT should be considered for patients with Philadelphia chromosome negative (Ph^-) disease who have MRD after induction therapy if a matched donor is available. Allogenic HSCT is preferred over autologous HSCT because of lower disease relapse rates.[51]

Relapsed Acute Lymphoblastic Leukemia

About 20% of children with ALL will relapse, but about 40% will experience long-term overall survival following relapsed treatment regimens.[10] In adults, about 30% to 60% of patients will relapse despite aggressive consolidation and maintenance chemotherapy.[52] The most common site for relapse is the bone marrow, although relapses can occur in the CNS, testicles, or multiple sites. Patients who have completed treatment and remained in remission for longer periods are more likely to achieve remission again.[11,41]

Clofarabine, a purine antimetabolite, is an option for patients with second or later relapses, but the duration of response is short. Single-agent clofarabine is associated with hepatotoxicity, prolonged myelosuppression, and febrile neutropenia.[53] Nelarabine, a T-cell-specific purine nucleoside analog, is approved to treat T-cell ALL who have relapsed disease following at least two prior therapies.[54] The drug is being evaluated in the frontline setting.[55] Adverse drug reactions such as severe peripheral and sensory neurotoxicity, severe somnolence, and seizures have occurred with nelarabine.[54]

Blinatumomab is approved for relapsed or refractory B-cell precursor ALL and in first or second CR with minimal residual disease (MRD) greater than or equal to 0.1%. As a bispecific T-cell engager (BiTE), blinatumomab binds to both CD19, an antigen present throughout B-cell development, and CD3, a T-cell receptor. By linking CD19 and CD3, blinatumomab enables a cascade of events resulting in lysis of CD19 cells.[56] Blinatumomab can induce a CR and achieve MRD negativity in adult and pediatric patients with relapsed or refractory ALL. In a randomized Phase 3 clinical trial, patients receiving blinatumomab had improved overall survival as compared to standard chemotherapy.[57] Blinatumomab has a short half-life and therefore must be administered as a continuous infusion for 28 days of a 6-week cycle. Adverse drug reactions occur in most patients, ranging from mild, reversible symptoms such as fever and rigors to more severe toxicities including neurotoxicity, infections, and cytokine release syndrome.[56]

Inotuzumab ozogamicin, an antibody-drug conjugate targeting CD22, received FDA approval in 2017 for relapsed or refractory B-cell ALL.[58] In a Phase 3 clinical trial, inotuzumab ozogamicin had significantly higher CR rates (80.7% vs 29.4%) compared to a standard chemotherapy group in patients with relapsed or refractory ALL. Positive responses occurred in patients with heavy disease burden and Ph^+ disease.[59] In a pediatric study, inotuzumab ozogamicin was evaluated in 51 children who received therapy in a compassionate use program. A CR was achieved in 67% of patients with overt marrow disease with most responders having MRD negativity.[60] Inotuzumab ozogamicin is associated with hepatotoxicity (including veno-occlusive disease [ie, sinusoidal obstruction syndrome]) and increased non-relapse mortality for patients who proceed to HSCT.[59]

Chimeric antigen receptor (CAR) T-cell therapy is a therapeutic option for ALL patients without other curative options. This novel therapeutic modality involves genetically engineered T cells that express CARs directed against CD19, resulting in T cells targeting leukemic cells that express CD19. In August 2017, the FDA-approved tisagenlecleucel, a CD19-directed autologous T-cell immunotherapy, for treatment of patients up to 25 years of age with B-cell ALL that is refractory or in second or later relapse.[61] An impressive 81% of children and young adults had a CR, many of which were durable.[62] The enthusiasm over CAR T-cell therapy based on its activity must be balanced by its significant adverse events and cost. Serious adverse drug reactions of CAR T-cell therapy include hypogammaglobulinemia, encephalopathy, seizures, and cytokine release syndrome (CRS), ranging from mild, flu-like symptoms to multiorgan system failure.[63] A single infusion of tisagenlecleucel is estimated to cost $475,000.[64] In October 2021, the FDA approved brexucabtagene autoleucel, an autologous anti-CD19 CAR T-cell therapy for adult patients with relapsed or refractory B-cell precursor ALL. In the ZUMA-3 trial, 83% of patients achieved a CR following brexucabtagene autoleucel. Adverse drug reactions were frequent with Grade ≥3 CRS and neurologic events occurring in 31% and 38% of patients, respectively.[65]

Allogeneic HSCT has traditionally been the treatment of choice for early bone marrow relapse (continuous CR less than 36 months) while children who relapse more than 36 months after completion of initial therapy have traditionally received chemotherapy alone.[10] The American Society for Transplantation and Cellular Therapy (ASTCT) guidelines recommend allogeneic HSCT for both standard- and high-risk ALL patients in first CR (CR1).[51] This recommendation is based on a meta-analysis of randomized trials that reported significantly reduced all-cause mortality with allogeneic HSCT in CR1 when compared to autologous HSCT.[66] For older patients, reduced-intensity conditioning (RIC) nonmyeloablative transplants may produce similar outcomes with less treatment-related morbidity and mortality.[67]

The decision for pediatric patients with relapsed ALL depends on the time from diagnosis to relapse and MRD at the end of reinduction. Patients who relapse <18 months since diagnosis are considered to have a *very early* relapse; these patients usually relapse while receiving their initial therapy. *Early* relapse occurs 18 months to 3 years; these patients relapse during maintenance or soon after finishing therapy. *Late* relapse occurs greater than 3 years from the start of their initial treatment. Patients are considered low risk if they have a late B-ALL marrow relapse with an end of reinduction marrow MRD < 0.1% or late isolated extramedullary relapse with an end of reinduction MRD < 0.1%. Intermediate risk patients have a late B-ALL marrow relapse with an end of reinduction MRD greater than or equal to 0.1% or late isolated extramedullary relapse with an end of reinduction RMD greater than or equal to 0.1%. Finally, high-risk patients have an early B-ALL marrow or isolated extramedullary relapse or T-ALL relapse. All patients receive the same four-drug reinduction regimen. Based on the end of reinduction MRD and risk stratification, patients may receive more chemotherapy for a total of 2 years, blinatumomab and HSCT, or continued reinduction cycles and HSCT. If a patient does not achieve MRD less than 0.01%, HSCT is not considered and alternative strategies such as investigational trials should be considered.[14]

ACUTE MYELOID LEUKEMIA

Risk Classification

⑦ Risk stratification for AML is based on patient-related and disease-related factors that influence a patient's likelihood of responding to drug therapy.[6] Early identification of these risk factors allows clinicians to personalize treatment according to the risk of disease recurrence. A key prognostic factor for AML is age. Patients aged 60 years and older have significantly worse outcomes than their younger counterparts. Older patients have differences in tumor biology which confers resistance and patient characteristics (eg, impaired performance status) that reduce treatment tolerance. Other unfavorable prognostic factors in adult AML include multidrug-resistance gene expression, WBC greater than 100,000 cells/mm^3 (100 × 10^9/L) and therapy-related AML.[68] Patients who develop "secondary" leukemia after treatment of another malignancy (ie, therapy-related AML) usually have a very poor response to antileukemic chemotherapy. Patient factors such as where patients received treatment, educational level, and cohabitation status may also affect treatment-related mortality.[69,70]

The genetic analysis includes karyotyping and molecular mutational profiling and provides important prognostic information (Table 157-3). For example, patients with core-binding factor with t(8;21)(q22;q22) or inv (16)(p13;q22)/t(16;16)(p13;q22) treated with a cytarabine-based regimen have a relatively favorable prognosis. Adults and children with chromosomal deletions such as 3q[abn(3q)] or 5q[del(5q)], monosomies of chromosome 5 or 7(−5/−7) have a poor prognosis with standard chemotherapy for AML and may be candidates for experimental treatments. About 40% of cases have a normal karyotype.[68] Molecular markers such as FMS-like tyrosine kinase 3 (FLT3), nucleophosmin 1(NPM1), c-KIT, DNA (cytosine-5)-methyltransferase (DNMT3), CEBPA, and isocitrate dehydrogenase 1 and 2 (IDH 1/2) can provide prognostic information and guide postremission therapy.[71]

TABLE 157-3

AML Risk Status According to Cytogenetics and Molecular Abnormalities

Risk	Cytogenetics	Molecular Abnormalities
Favorable	Inv(16) t(8;21) t(15;17)	NPM1 mutation in the absence of FLT3-ITD or presence of FLT3-ITD$^{\text{low}}$ Biallelic CEBPA mutation
Intermediate	Cytogenetics abnormalities not classified as favorable or poor t(9;11)	Core binding factor with KIT mutation Mutated NPM1 and FLT3-ITD$^{\text{high}}$ WT-NPM1 without FLT3-ITD$^{\text{low}}$
Poor risk	Complex (≥3 clonal chromosomal abnormalities Monosomal karyotype -5, 5q, -7, 7q- 11q23 Inv(3) t(6;9) t(9;22)	Normal cytogenetics with FLT3-ITD Mutated TP53 Mutated RUNX1 Mutated ASXL WT-NPM1 and FLT3-ITD$^{\text{high}}$

AML, acute myeloid leukemia; ASXL, additional sex combs; FLT-3-ITD, Fms-like tyrosine kinase 3 internal tandem duplication; NPM1, nucleophosmin; RUNX1, Runt-related transcription factor 1; TP53, tumor protein.

Data from Dohner H, Estey E, Grimwade D, et al. Blood. 2017;129:424-447. National Comprehensive Cancer Network Clinical Practice Guidelines in Oncology. Acute Myeloid Leukemia. Version 3.2021. Accessed November 15, 2021.

Two major types of FLT3 mutations have been identified—internal tandem duplications (ITD) and tyrosine kinase domain (TKD) point mutations.

Patients with FLT3-ITD mutations have shorter remission durations and worse survival outcomes.[71,72] FLT3-ITD mutations occur in about 15% of older patients and 25% of patients younger than 60 years.[73] *NPM1* mutations occur in about 30% of patients with AML, even in patients with normal karyotype, and commonly coexists with FLT3. They are associated with a higher CR and reduced relapse risk as compared to patients without the mutation. c-KIT mutations have been observed in about 20% of patients with core-binding factor AML and are associated with decreased duration of CR and overall survival.[69,74] CEBPA mutations occur in about 10% of patients with AML. The most common CEBPA mutation, a biallelic (double) mutation, is associated with improved prognosis.[8] IDH1/2 mutations occur in <10% of patients and its effect on prognosis is unclear.[69]

Prognostic factors associated with pediatric AML include response to the first course of remission induction therapy, cytogenetics, and molecular genetics. Poor prognostic factors include monosomy 7, age older than 10 years, black race, internal tandem duplications of FLT3, *MLL* gene rearrangements, and a diagnosis of AML secondary to prior chemotherapy or radiation therapy. Conversely, inversion of chromosome 16, trisomy 21, CBF-AML, *PML-RARA*, *NPM1*, biallelic CEBPA, and *RUNX1-RUNX1T1* fusion transcript t(8;21) are associated with a favorable outcome.[75]

Treatment—Acute Myeloid Leukemia

Desired Outcomes

The short-term goal of treatment for AML is to rapidly achieve a complete clinical and hematologic remission. In the absence of a CR, a rapid and fatal outcome is inevitable. After a CR is achieved, the goal is to maintain the patient in continuous CR.[72,73] The occurrence of leukemic relapse in the bone marrow significantly reduces the likelihood of cure. Upon relapse, available clinical trials, additional chemotherapy, or best supportive care should be pursued depending on the patient’s clinical status.[72] Most patients who will die from acute leukemia die within the first 6 years. Survival curves tend to plateau after that time, and patients alive without disease are considered to be cured of their leukemia.

With recent advances in antineoplastic therapy and supportive care, 20% to 40% become long-term survivors. Overall, the median duration of remission is 1 to 2 years.[74] In contrast to ALL, effective therapies utilized in AML result in severe and often prolonged myelosuppression. As a result, patients with AML, particularly patients older than 60 years, are at greater risk for treatment-related fatal infectious and bleeding complications.

Treatment Phases

Therapy for AML is divided into two phases: (a) induction and (b) postremission therapy (eg, consolidation, intensification) (Fig. 157-2).

Induction

⑧ As with ALL, the goal of remission induction for AML is to rapidly induce a CR, defined as the disappearance of all clinical and bone marrow evidence (normal cellularity more than 20% with less than 5% blasts) of leukemia, with restoration of normal hematopoiesis (neutrophils more than or equal to 1,000 cells/mm^3 [1 × 10^9/L] and platelets more than 100,000 cells/mm^3 [100 × 10^9/L]). Partial remission is a significant response to treatment (a decrease of at least 50% of blasts). Evidence of residual disease in the bone marrow (5%-25% blasts) is considered a treatment failure requiring additional therapy. The definition of CR has several categories, including CR (morphologic CR with restoration of normal hematopoiesis), CR with incomplete hematological recovery (CRi), cytogenetic CR ([CRc] patient with normal cytogenetics in which cytogenetics were previously abnormal), and molecular CR ([CRm] molecular studies negative). A bone aspirate/biopsy should be obtained 14 to 21 days after the start of induction therapy to assess for response.[72]

A CR is achieved in 60% to 85% of adults aged 60 years or younger. Compared to ALL, however, the CR rate is lower with AML. Because the CR rate in AML is related to the intensity of the remission induction regimen, the drugs used in AML are given at doses that uniformly cause severe myelosuppression (except tretinoin). One reason for the lower CR rate in AML as compared to ALL is the inability to give optimal doses of chemotherapy because of marrow toxicity. With continued improvement of supportive care, more intensive treatment regimens are given to reduce the high rate of leukemic relapse and increase the proportion of long-term survivors. Most patients achieve a CR after one or two courses of chemotherapy. Patients who require additional chemotherapy to achieve a CR have been reported to have a poor prognosis, even if remission is ultimately achieved.

The most active single agents in AML are the anthracycline antibiotics (daunorubicin, doxorubicin, and idarubicin), mitoxantrone, and the antimetabolite cytarabine. The standard therapy for the treatment of adult AML has not changed in several decades. The most common regimen ("7+3") combines daunorubicin administered as a short infusion of 60 to 90 mg/m^2/day on days 1 to 3, along with cytarabine administered as a continuous 24-hour infusion of 100 to 200 mg/m^2/day on days 1 to 7.[6,72] The CR rate with the 7+3 regimen is 65% to 75% in patients aged 18 to 60 years. Several trials have attempted to improve on conventional 7+3 therapy, but have shown no improvement by (a) increasing cytarabine to 10 days, (b) shortening cytarabine to 5 days, (c) substituting doxorubicin, idarubicin, or mitoxantrone for daunorubicin, (d) adding other agents such as etoposide, thioguanine, or topotecan, or (e) increasing cytarabine to higher doses (2 g/m^2 every 12 hours for 8-12 doses).[72] The most recent change to the standard 7+3 regimen is to increase the daunorubicin dose. Adults younger than 60 years with AML who were randomized to receive higher daunorubicin dosages (90 mg/m^2/day on days 1-3) in combination with 7 days of standard-dose cytarabine (100 mg/m^2/day) had a significantly higher CR rate (71% vs 57%) and longer median overall survival (23.7 vs 15.7 months) as compared with those who received the standard 7+3 regimen of daunorubicin (45 mg/m^2/day on days 1-3) and cytarabine. However, on subgroup analysis, the survival benefit with high-dose daunorubicin was restricted to patients with favorable or intermediate-risk cytogenetics and those younger than 50 years.[76]

Idarubicin and mitoxantrone have been evaluated as alternatives to daunorubicin in combination with standard-dose continuous infusion cytarabine. Trials in younger patients reported improved CR rates with these newer anthracyclines (idarubicin) or anthracenediones (mitoxantrone), and one trial reported prolonged survival. Among older adults, the CR rate and overall survival are not different among the different anthracyclines or anthracenediones.[74] Therefore, the anthracycline of choice for the standard 7+3 regimen is daunorubicin or idarubicin (12 mg/m^2) and many centers adopt idarubicin or higher doses of daunorubicin into the induction regimen in younger AML patients.

Based on experimental tumor models that showed a steep dose-response curve for cytarabine, higher cytarabine doses have been evaluated to increase its antileukemic activity. The decision to give high-dose cytarabine during induction depends on the treatment plan for postremission or consolidation therapy. In a study of patients aged 15 through 60 yearswith AML, the cytarabine dose (conventional dose versus high-dose) in the remission induction regimen (with both cohorts receiving daunorubicin and etoposide) was evaluated in a treatment protocol that did not include high-dose cytarabine as consolidation.[77] Patients who received high-dose cytarabine had higher remission rates and longer overall survival, particularly in patients younger than 46 years. A retrospective study conducted by the European Group for Blood and Marrow Transplantation reported that the cytarabine dose administered during induction and/or consolidation does not influence the outcome in patients who ultimately received allogeneic or autologous HSCT.[78] These data suggest that high doses of cytarabine during induction may not be needed in patients who receive HSCT as postremission therapy. In summary, the role of high-dose cytarabine during induction remains controversial. If used during induction, high-dose cytarabine is more appropriate in younger patients than in older patients because of poor tolerance by older patients. In addition, it may be an option in patients unable to tolerate anthracyclines.

A novel remission induction option has emerged for patients with poor prognosis AML. In August 2017, the FDA granted regular approval to a liposome-encapsulated combination of daunorubicin and cytarabine (CPX-351) to treat adults with newly diagnosed therapy-related AML or AML with myelodysplasia-related changes.[79] Approval was based on an open-label phase 3 trial of newly diagnosed high-risk AML patients aged 60 to 75 years who were randomized to receive the standard 7+3 regimen or CPX-351 for one to two cycles of induction followed by similar consolidation. The CPX-351 induction course consisted of 100 units/m^2 (100 mg/m^2 cytarabine and 44 mg/m^2 daunorubicin) administered as a 90-minute infusion on days 1, 3, and 5. Patients who received CPX-351 had significantly higher CR rates (37.3% vs 25.6%) and overall remission rates (47.7% vs 33.3%) as compared to those receiving the standard 7+3 regimen.[80] Adverse drug reactions associated with CPX-351 include hemorrhagic events, febrile neutropenia, rash, fatigue, and increased risk of infections. Since CPX-351 includes daunorubicin, cardiotoxicity remains a concern and clinicians should monitor cardiac function.[79]

Another recent addition to remission induction therapy is gemtuzumab ozogamicin, which was withdrawn from the United States market in 2010 because no survival benefit and increased treatment-related mortality were observed in the pivotal trial. Subsequent trials evaluated lower doses of gemtuzumab ozogamicin.[81] In a Phase 3 trial, patients were randomized to receive daunorubicin (60 mg/m^2 days 1-3) and cytarabine (200 mg/m^2 days 1-7) with or without gemtuzumab ozogamicin (days 1, 4, and 7) for the treatment of adults with newly diagnosed *de novo* AML. Patients in the gemtuzumab ozogamicin group had significantly longer median event-free survival (17.3 vs 9.5 months) as compared with those in the daunorubicin and cytarabine group, but also a higher risk of grade 3 or higher adverse drug reactions (infection, hemorrhage, veno-occlusive disease, and thrombocytopenia).[82]

Several small molecule FLT3 inhibitors have been developed and are changing the AML treatment landscape.[83] Midostaurin is an oral multitargeted TKI that is active against FLT3. In a large phase 3 trial, patients younger than 60 years with AML and an *FLT3* mutation were randomly assigned to receive standard remission induction with daunorubicin and cytarabine plus either midostaurin or placebo. Patients who remained in remission after consolidation therapy received either midostaurin or placebo as maintenance therapy. Patients in the midostaurin arm had a significant improvement in overall survival (74.7 vs 25.6 months).[84] Midostaurin is administered days 8 to 21 of each cycle of induction chemotherapy and during each consolidation cycle.[85]

The NCCN guidelines recommend the standard 7+3 regimen for AML patients younger than 60 years. Younger patients with intermediate-risk disease cytogenetics with *FLT3*-mutant disease should receive 7+3 therapy combined with midostaurin. Patients with therapy-related AML should receive standard 7+3 as remission induction, but CPX-351 administered on days 1, 3, and 5 for one cycle is a recommended alternative option.[72]

Older patients (more than or equal to 60 years) who are not candidates for intensive remission induction therapy should be offered venetoclax, an oral BCL-2 inhibitor, once daily with ramp-up dosing with a hypomethylating agent such as azacitidine or decitabine.[72,86] Azacitidine and decitabine are pyrimidine nucleoside analogs of cytidine that inhibit DNA methylation. While each agent has shown promising results versus conventional chemotherapy and best supportive care, the agents have not been compared to each other in trials.[86,87] Azacitidine is usually given IV or SQ for 7 days while decitabine is given IV for 5 days. Cycles are repeated every 28 days. Median overall survival was increased 4 months with azacitidine compared to standard induction chemotherapy (10.4 vs 6.5 months).[88] These agents are generally well-tolerated with the most significant adverse drug reaction being myelosuppression. Best supportive care includes the use of blood product transfusion support.

Other options for older patients who are not candidates for intensive remission induction therapy include gemtuzumab ozogamicin in CD33-positive patients and IDH inhibitors for patients with IDH1/2 mutations.[72] A single remission induction course of gemtuzumab on days 1 and 8 improves overall survival as compared to best supportive care.[89] Ivosidenib (IDH1 inhibitor) and enasidenib (IDH2 inhibitor) are both FDA approved for relapsed/refractory AML.[90] These agents are evaluated in combination with hypomethylating agents in the frontline setting. A novel oral hedgehog pathway inhibitor, glasdegib, is approved in combination with low-dose cytarabine for patients ≥ 75 years who cannot tolerate intensive remission induction therapy.[91]

The NCCN guidelines recommend venetoclax, in combination with decitabine or azacytidine, in AML patients ≥ 60 years who are not candidates for intensive induction therapies.[72] Venetoclax is associated with tumor lysis syndrome (TLS), and patients should have a WBC <25,000 cells/mm^3 (25 x 10^9/L) prior to initiation.[92] Clinicians should provide prophylactic strategies such as hydration and anti-hyperuricemic therapies and monitor blood chemistries (uric acid, potassium, phosphorus, and calcium).

All adult patients who present with CNS symptoms or asymptomatic monocytic disease should have a diagnostic lumbar puncture and should be treated for disease if it is positive. Methotrexate or cytarabine should be administered intrathecally twice a week until clearance of leukemic blasts from the CSF, and then weekly for 4 to 6 weeks. Continued secondary prophylaxis is recommended following treatment for CNS disease.[72]

Postremission Therapy

⑧ Although most adults with AML achieve a CR, the duration of remission is short (6-9 months) if no further treatment is given. Relapse is presumably a consequence of the presence of residual, but clinically undetectable, leukemic cells after remission induction therapy. The goal of intensive postremission therapy is to eradicate these residual leukemic cells and prevent the emergence of drug-resistant disease. The need for postremission therapy is based on postmortem analysis and cell kinetic data suggesting that nearly 10^9 residual leukemic cells remain after effective remission induction therapy. Strategies evaluated as postremission therapy include (a) low-dose, prolonged maintenance therapy, (b) short-course intensive chemotherapy-alone regimens, and (c) high-dose chemotherapy followed by allogeneic or autologous HSCT.

In the treatment of AML, intensive postremission therapy is referred to as consolidation therapy. Results of randomized controlled trials in adults clearly show that intensive postremission therapy following remission induction therapy prolongs survival versus no therapy, although the exact duration of postremission therapy is controversial.[6,74]

The intensity of postremission therapy is important. In a large CALGB trial, all patients who achieved a CR after standard 7+3 induction were randomized to receive one of the three cytarabine-based consolidation regimens: 100 mg/m^2/day or 400 mg/m^2/day as a continuous 24-hour infusion, or 3,000 mg/m^2 every 12 hours on days 1, 3, and 5. For adults younger than 60 years, the probability of remaining in CR after 4 years was significantly higher in patients who received high-dose cytarabine (25% vs 29% vs 44%, respectively). Older patients had lower response rates in all arms and did not benefit from the higher cytarabine doses, probably because they could not tolerate the high-dose regimen. Dose-limiting neurotoxicity in the high-dose arm was more common in older patients and those with impaired renal function.[93]

High-dose cytarabine is an essential component of postremission therapy, particularly if it is not used in induction therapy. However, many questions remain, such as the optimal dose (g/m^2), number of doses per cycle, and number of cycles of high-dose cytarabine. Among patients with core-binding factor AML, defined as the presence of either t(8;21) or inv(16), multiple cycles are beneficial. The NCCN guideline recommends three to four cycles of high-dose cytarabine for adults younger than 60 years with favorable cytogenetics. Patients with intermediate-risk cytogenetics should receive three to four cycles of high-dose cytarabine or proceed directly to a matched sibling or alternative donor HSCT.[72] For those patients with FLT3-positive AML, midostaurin on days 8 to 21 should be added to high-dose cytarabine.[83,84] Gemtuzumab ozogamicin, in combination with daunorubicin and cytarabine, is an option for patients with CD33-positive, intermediate-risk cytogenetics AML.

If the patient is 60 years of age or older, standard-dose cytarabine with or without an anthracycline for one to two cycles, a reduced-dose high-dose cytarabine regimen (1-1.5 g/m^2/day for 4-6 doses) for one to two cycles, continuation of low-intensity therapy such as azacitidine or decitabine, or enrollment in a clinical trial is recommended. The reduced dose of high-dose cytarabine in older patients is related to their reduced ability to tolerate cytarabine and the higher risk of neurotoxicity. Patients with high-risk cytogenetics, underlying MDS, or secondary AML should either be enrolled in a clinical trial or be referred for either a matched sibling or alternative donor allogeneic HSCT.[72]

After remission is achieved, maintenance therapy with oral azacitidine (days 1-14 of a 28-day cycle) is recommended for patients <60 years old with intermediate or unfavorable cytogenetics.[72] In a Phase 3 trial of patients >55 years old who were in CR1, oral azacitidine improved overall survival (24.7 vs 14.8 months) as compared to placebo. Common grades 3/4 adverse drug reactions associated with oral azacitidine are neutropenia and thrombocytopenia.[94]

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic HSCT is the most aggressive postremission therapy in the management of AML. This treatment approach is controversial, specifically the appropriateness, timing, treatment design, and donor selection.

The antileukemic activity of allogeneic HSCT is based on the administration of pretransplant high-dose chemotherapy and the development of a posttransplant immune-based antileukemic response. The immune-based response, referred to as a graft-versus-leukemia (GVL) effect, often accompanies the graft-versus-host disease (GVHD) reaction. Evidence for the immune-based benefit of allogeneic HSCT is based on the observation of consistently lower relapse rates with allogeneic HSCT as compared to autologous or syngeneic HSCT. This potential benefit of allogeneic HSCT can be offset by the risk of posttransplant complications such as GVHD, sinusoidal obstruction syndrome, graft failure, and infections.

Allogeneic HSCT was first evaluated as a treatment modality for AML in refractory patients, but because of initial success in small numbers of patients, it has also been evaluated as intensive-postremission therapy in AML patients in first or subsequent remission.[95] Transplant-related mortality following HLA-matched sibling allogeneic HSCT ranges from 10% to 25%. However, these data are based on studies of HSCT with HLA-identical sibling donors. With increasing use of matched unrelated donors and umbilical cord blood as donor sources, transplant-related mortality of allogeneic transplants continues to be evaluated. With the availability of more effective immunosuppressive and antibiotic regimens, transplant-related mortality has decreased and survival has increased.[96]

Allogeneic HSCT from an HLA-matched sibling donor for AML patients in CR1 results in long-term event-free survival in 43% to 55% of patients. Although the results vary, some of the studies show longer event-free survival and lower relapse rates with allogeneic HSCT in AML in CR1 as compared to chemotherapy-alone postremission regimens. Single center prospective trials have not shown an overall survival advantage for allogeneic HSCT in all patients with AML CR1. Meta-analyses of clinical trials comparing allogeneic HSCT to other consolidation strategies in CR1 show that allogeneic HSCT does provide an overall survival advantage for patients with intermediate- and high-risk AML. The ASTCT recommends allogeneic HSCT for AML patients who are in CR1 with intermediate- or high-risk disease and CR2 patients.[51]

Myeloablative allogeneic HSCT is generally restricted to patients younger than 60 years, which limits the number of patients eligible for treatment of a disease that primarily affects older adults. Non-myeloablative transplantation (NMT) uses RIC preparative regimens and is now being used in AML patients, particularly in older patients and those with comorbid illnesses that would limit their eligibility for conventional allogeneic HSCT.[97] NMT is designed to provide enough immunosuppression in the preparative regimen to allow for engraftment of donor cells and depends primarily on the development of a GVL effect as a means to treat and prevent relapse of AML. The procedure is well tolerated in a wide age range of patients, with low rates of regimen-related toxicity. In a large study of 1,637 patients who received NMT, age was not associated with outcome.[98] Registry data of patients aged 70 years or older (89% received NMT) reported that 2-year overall survival significantly improved between 2000-2007 and 2008-2013 (26% vs 39%).[99]

Given that only 30% of patients have an HLA-matched sibling donor, matched unrelated donor HSCT is also an option for children and younger adults with AML. This approach is associated with improved survival, but the risk of transplant-related mortality is higher than in patients undergoing HLA-matched sibling allogeneic HSCT. A large observational study of matched unrelated donor transplants indicates that overall survival, nonrelapse mortality, and relapse rate have improved over the last two decades.[100]

Autologous Hematopoietic Stem Cell Transplantation

Compared to allogeneic HSCT, autologous HSCT has the advantages of a lower risk of posttransplant complications because of lack of immunosuppression and GVHD, and more broad applicability because of a lack of donor limitations and fewer age restrictions. Although the preparative regimen still provides antileukemic activity, autologous HSCT is associated with a higher risk of relapse because of a lack of a GVL effect and potential tumor contamination with autologous stem cells. The ASTCT does not recommend autologous HSCT in pediatric patients.[51] Autologous HSCT is an alternative option in adults, particularly in low-risk patients but should not be pursued in patients with high-risk cytogenetics.[51,101] The NCCN guideline does not recommend autologous HSCT outside the setting of a clinical trial.[72]

Postremission Therapies

Several randomized trials in AML patients in CR1 have compared outcomes following allogeneic HSCT, autologous HSCT, or intensive consolidation chemotherapy.[101] In most trials, eligible patients based on age and donor availability received an allogeneic HSCT and the remaining patients were randomized between autologous HSCT and chemotherapy alone. The effect of stem cell source (bone marrow or peripheral blood) on event-free and overall survival has been evaluated in several trials. The ASTCT recommends bone marrow grafts with myeloablative conditioning regimens given comparable survival with a lower risk of chronic GVHD. Peripheral blood may offer improved leukemia-free survival for patients who receive RIC, but additional prospective trials are needed.[96]

The decision to transplant is often based on the cytogenetic risk category.[69] Allogeneic HSCT is the treatment of choice in patients with high-risk cytogenetics because they do poorly with conventional chemotherapy or autologous HSCT. Patients with favorable-risk cytogenetics should not proceed to transplant in CR1, as neither autologous nor allogeneic HSCT is superior to conventional chemotherapy. The optimal treatment of choice in patients with intermediate-risk cytogenetics is not clear and is based on the availability of a matched-related donor and clinician preference. Despite recommendations that patients with intermediate-risk cytogenetics should receive HSCT in CR1, a recent study reported only 27% of patients in a European study proceeded to transplant at CR1.[102]

For patients 60 years and older, additional consolidative chemotherapy or immediately proceeding to HSCT is recommended if the patient has achieved a CR1 and is deemed a suitable transplant candidate. The NCCN guideline recommends NMT rather than a myeloablative transplant in this patient population. For the AML patient who relapses early after induction therapy, if a sibling or matched unrelated donor is available, then allogeneic HSCT is the primary reinduction therapy because conventional chemotherapy offers little benefit. If the relapse occurs late, then HSCT may be used as postremission consolidation after reinduction therapy. In those patients who achieve remission with an intensive regimen but experience significant toxicities, the use of maintenance hypomethylating agents (eg, decitabine or azacitidine) every 4 to 6 weeks until progression is an option.[72]

Acute Myeloid Leukemia in Children

AML comprises about 20% of leukemias in children and adolescents. Most cases of AML in children arise *de novo* but AML is associated with trisomy 21, Fanconi anemia, dyskeratosis congenital, Schwachman-Diamond syndrome and Kostmann syndrome. Secondary AML is extremely rare in children and is associated with alkylating agents, topoisomerase inhibitors and radiation therapy.[12] AML patients are classified as low risk or high risk based on molecular and cytogenetic markers and response to therapy. Examples of low-risk cytogenetic and molecular markers (ie, favorable prognostic markers) are PML-RARA, inv(16), RUNX1, CEBPα, and NPM1 and examples of high-risk markers (unfavorable prognostic markers) are monosomy 5, monosomy 7, KMT2A (MLL), FLT3/ITD with allelic ratio greater than 0.1%, and rearrangement or loss of ETV6.[103] The CR rate in pediatric AML is high at about 90%, with an event-free and overall survival of 45% and 65%, respectively. Unfortunately, relapse occurs in nearly half of pediatric AML patients. Even in low-risk children, the relapse rate is about 35%. Children with high-risk genetic features are at highest risk of relapse and only one in three are alive at 3 years.

Therapy for AML in children includes one to two cycles of induction therapy followed by two to three cycles of consolidation therapy. The number of cycles varies by protocol. Induction therapy with cytarabine and an anthracycline is standard. Etoposide is often included in induction but its contribution to efficacy is unclear.[104] Gemtuzumab ozogamicin was FDA approved for newly diagnosed CD33-positive AML patients aged 1 month and older. It has been incorporated into the standard backbone in Children's Oncology Group trials of children with newly diagnosed AML.[105] Consolidation therapy or intensification phases of treatment involve the use of high-dose cytarabine in combination with an anthracycline and etoposide.[13] Maintenance therapy has no role in pediatric AML (see Fig. 157-2). Intrathecal chemotherapy for CNS prophylaxis is routinely used, but the optimal regimen is unknown and varies by protocol.[75] Cranial radiation is only used for patients with refractory CNS disease.

Certain patients may be eligible to receive an HSCT as consolidation therapy instead of continued chemotherapy. The use of HSCT in CR1 rather than waiting until relapse/CR2 is controversial. Most trials recommend consolidation with chemotherapy for favorable-risk patients. The role of HSCT in unfavorable or high-risk patients has been utilized in recent childhood AML studies upfront.[106]

Relapsed or Refractory Acute Myeloid Leukemia

Treatment of relapsed or refractory AML is a therapeutic challenge despite the emergence of novel agents and the increasing number of available donors for HSCT. The most common cause of treatment failure in AML patients receiving chemotherapy alone or undergoing HSCT is relapse. In addition, many patients, particularly older patients, have refractory disease as defined by the inability to achieve a CR after two courses of induction therapy. In most cases, the preferred method of treatment for relapsed or refractory disease is HSCT if patients can tolerate it. Unfortunately, most patients receive salvage chemotherapy because only a small percentage of relapsed or refractory adult patients will be eligible for HSCT, particularly allogeneic HSCT because of age and donor restrictions.

Commonly used salvage chemotherapy regimens include FLAG-IDA (fludarabine, cytarabine, idarubicin, and granulocyte colony stimulating factor), MEC (mitoxantrone, etoposide, cytarabine), and GCLAC (clofarabine, high-dose cytarabine, and priming granulocyte colony stimulating factor). These regimens are associated with CR rates of 40% to 65% in younger patients and significant toxicity.[107] Patients who achieve a CR2 should pursue an allogeneic HSCT since this modality is the only potentially curative therapy. Allogeneic HSCT should be performed when a patient is in CR to allow for a robust GVL effect.

In patients unfit to receive intensive salvage chemotherapy, less-aggressive therapies such as hypomethylating agents (azacitidine, decitabine) are options.[72] In a large multicenter retrospective study of hypomethylating agents in relapsed/refractory AML, 11% of patients achieved a CR with a median overall survival of 6.7 months.[108] Given these poor outcomes with current options, older or unfit patients with relapsed or refractory AML are encouraged to enroll in clinical trials.[72]

Several novel classes of agents are treatment options for relapsed or refractory AML including FLT-3 inhibitors (eg, midostaurin, gilteritinib), IDH (eg, enasidenib, ivosidenib), Hedgehog inhibitors (glasdegib) and BCL-2 inhibitors (venetoclax). Table 157-4 lists novel oral agents for AML. These agents are given either as single agents or combined with other agents such as low-dose cytarabine and hypomethylating agents. Immunotherapy approaches such as CAR T-cells, BiTEs, antibody-drug conjugates, and cell-based vaccines are being investigated in clinical trials.[109]

TABLE 157-4

Novel Oral Therapies for Acute Myeloid Leukemia

Agent	Class	Dosing	FDA Indication	Drug Interactions
Midostaurin	FLT3 inhibitor	50 mg PO twice daily with food	Newly diagnosed AML that is FLT3 mutation positive as detected by an FDA-approved test, in combination with standard cytarabine and daunorubicin induction and cytarabine consolidation	• Strong CYP3A4 inhibitors; consider alternative therapies • Avoid concomitant CYP3A4 inducers • CYP2B6, BCRP, OATP1B1 substrates; dose adjustment may be necessary
Gilteritinib	FLT3 inhibitor	120 mg PO once daily	Treatment of adult patients who have relapsed or refractory AML with a FLT3 mutation as detected by an FDA-approved test	• Strong CYP3A inhibitors; consider alternative therapies • Avoid concomitant P-gp and strong CYP3A inducers
Enasidenib	IDH inhibitor	100 mg PO once daily	Treatment of adult patients with relapsed or refractory AML with an isocitrate dehydrogenase-2 (IDH2) mutation as detected by an FDA-approved test	Decrease the dose of OATP1B1, OATP1B3, and BCRP substrates
Ivosidenib	IDH inhibitor	500 mg PO once daily with or without food	• Newly diagnosed with IDH1 mutation positive AML who are ≥ 75 years old or who have comorbidities that preclude use of intensive induction chemotherapy • Relapsed or refractory AML IDH1 mutation positive	• Avoid concomitant CYP3A4 inducers • Avoid concomitant CYP3A4 substrates • Strong or moderate CYP3A4 inhibitors; reduce ivosidenib dose to 250 mg/day if given with strong CYP3A4 inhibitor • QTc prolonging drugs
Glasdegib	Hedgehog inhibitor	100 mg PO once daily	Treatment of newly diagnosed AML in adult patients who are ≥75 years old or who have comorbidities that preclude use of intensive induction chemotherapy (in combination with low dose cytarabine)	• Avoid concomitant strong and moderate CYP3A4 inducers • Strong CYP3A4 inhibitors; consider alternative

				therapies • QTc prolonging drugs
Venetoclax	BCL-2 inhibitor	Day 1: 100 mg PO once daily Day 2: 200 mg PO once daily Day 3: 400 mg PO once daily Day 4 and beyond: 400 mg PO once daily of each 28-day cycle in combination with azacitidine or decitabine; 600 mg PO once daily of each 28-day cycle in combination with low-dose cytarabine	Treatment of newly diagnosed AML in adult patients who are ≥75 years old, or who have comorbidities that preclude use of intensive induction chemotherapy (in combination with azacitidine, or decitabine, or low-dose cytarabine)	• Avoid concomitant strong and moderate CYP3A4 inducers • Strong or moderate CYP3A inhibitors or P-gp inhibitors; adjust dosage of venetoclax • P-gp substrates, take 6 hours prior to venetoclax
Azacitidine	Nucleoside metabolic inhibitor	300 mg PO once daily on days 1 through 14 of each 28-day cycle	Treatment of adult patients with AML who achieved first complete remission or complete remission with incomplete blood count recovery following intensive induction chemotherapy and are not able to complete intensive curative therapy	Coadministration with omeprazole increased azacitidine AUC by 19%

BCRP, breast cancer resistance protein; CYP, cytochrome P43550; P-gp, P-glycoprotein; OATP, organic anion-transporting polypeptide.

Treatment—Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APL) is a subclass of AML that accounts for about 10% of all cases. APL is the most curable AML subtype, but its clinical presentation is associated with a high early death rate secondary to coagulopathy.[110] Most patients are diagnosed between the ages of 15 and 60 years, and the average age is 44 years.[72] Although the management of APL is complex, remission induction regimens produce CR rates exceeding 90% with 5-year event-free survival rates of 70% to 80%.[111] APL is clinically unique from the other subclasses because of the common occurrence of severe coagulopathy (characterized by disseminated intravascular coagulation) at diagnosis and during induction therapy, which frequently results in intracerebral hemorrhage. In APL, differentiation and maturation arrest are caused by alterations in the retinoic acid receptor (RAR) because of the translocation of chromosomes 15 and 17. The discovery of t(15;17) provides a cytogenetic marker of the disease and is predictive of response to differentiation therapy with tretinoin (commonly referred to as all-*trans* retinoic acid or ATRA). This translocation leads to a fusion protein of the *PML* gene on chromosome 15 and the RARα on chromosome 17.

Before the availability of tretinoin in the late 1980s, treatment of APL consisted of the same combination chemotherapy regimens used in the treatment of other subclasses of AML. Such standard regimens produced CR rates of 50% to 60% but were associated with high treatment–related mortality caused by hemorrhagic complications. The introduction of targeted therapy with tretinoin results in high CR rates with a lower risk of life-threatening bleeding complications. Arsenic trioxide targets the PML moiety, resulting in apoptosis, and is synergistic with tretinoin.[112] The initial WBC count at presentation is the most important prognostic factor in patients with APL. Risk stratification of patients at diagnosis based on WBC count has improved outcomes. Abnormal creatinine, increased peripheral blast count, and coagulopathy are risk factors associated with early death due to hemorrhage.[113]

Treatment Phases

Induction Therapy

9 Tretinoin, an oral vitamin A analog, is given orally in a dose of 45 mg/m^2/day, as a single dose or divided into two doses, after a meal. Tretinoin-based regimens achieve CR rates as high as 95% in APL patients within 1 to 3 months. Because tretinoin does not cross the blood-brain barrier, leukemic meningitis should be treated with conventional intrathecal chemotherapy.

Although it is not myelosuppressive, tretinoin therapy is associated with headache, skin and mucous membrane reactions, bone pain, nausea, and retinoic acid syndrome. When tretinoin is started, rapid onset of differentiation of promyelocytes occurs, which can lead to leukocytosis and retinoic acid syndrome. The retinoic acid syndrome (unexplained fever, acute respiratory distress, interstitial pulmonary infiltrates, pleural effusions, and weight gain) is now referred to as APL differentiation syndrome (or APL hyperleukocytosis syndrome) because it is associated with other treatment modalities in the management of APL. The syndrome is fatal in 5% to 29% of cases. A combination of chemotherapy with tretinoin induction decreases the risk of APL differentiation syndrome, and rapid initiation of dexamethasone 10 mg (0.2 mg/kg per dose in children) twice daily on development of symptoms decreases associated mortality.[113]

For newly diagnosed low-risk APL patients (WBC ≤10,000/mm^3 [10 × 10^9/L]), induction therapy should consist of tretinoin 45 mg/m^2 in two divided doses daily in addition to arsenic trioxide (ATO) 0.15 mg/kg IV daily until hematologic CR.[72] This “chemotherapy-free” strategy achieved an impressive 100% CR rate in a Phase 3 clinical trial. Furthermore, early mortality and hematological toxicities were significantly less with patients who received tretinoin + ATO compared to those who received tretinoin and chemotherapy.[113] For patients with adequate cardiac function, the combination of daily tretinoin and idarubicin 12 mg/m^2 on days 2, 4, 6, and 8 is also a recommended alternative regimen. Assessment of response to treatment of APL is completed when the bone marrow has recovered after induction therapy. A 28- to 35-day bone marrow biopsy is recommended to document morphologic remission before consolidation.[72] ATO induces clinical remissions in APL through its induction of apoptosis and differentiation.

ATO therapy is associated with two specific adverse drug reactions. First, it can cause the APL differentiation syndrome, similar to tretinoin. Management is similar: corticosteroids at first signs of pulmonary distress or a rapidly rising WBC count. The second adverse drug reaction is prolonged QT$_c$ interval. It is important to obtain a baseline 12-lead electrocardiogram before starting therapy with ATO and correct any electrolyte abnormalities, including potassium, calcium, and magnesium. Other medications known to prolong the QT$_c$ interval should be avoided, if possible, during arsenic trioxide therapy. The QT$_c$ interval should not exceed 500 ms at baseline, and if it increases to more than 500 ms during therapy, the patient should be reevaluated. ATO should not be restarted until the QT$_c$ is less than 460 ms.

High-risk patients (WBC > 10,000/mm^3 [10 × 10^9/L]) represent about 30% of APL patients. They should proceed with induction therapy that consists of tretinoin in addition to an anthracycline. All of these regimens include tretinoin 45 mg/m^2/day until a CR is achieved, in combination with an anthracycline (either daunorubicin or idarubicin) or tretinoin plus ATO for patients unable to tolerate anthracycline therapy. Several induction regimens also contain cytarabine; similar CR rates are observed with daunorubicin or idarubicin.[72] APL cells are more sensitive to anthracyclines, possibly because of decreased P-glycoprotein expression. Gemtuzumab ozogamicin has been added to tretinoin and anthracycline combinations for high-risk patients but does not increase event-free or overall survival.[114]

Consolidation Therapy

Due to a high relapse rate, all APL patients should receive consolidation therapy. The NCCN guideline recommends ATO 5 days/week for 4 weeks every 8 weeks for four cycles in addition to tretinoin 45 mg/m^2/day for 2 weeks every 4 weeks for seven cycles in low-risk patients. If ATO is unavailable or contraindicated, low-risk patients should receive tretinoin in combination with an anthracycline in consolidation. In high-risk patients, consolidation therapy consists of multiple cycles of ATO and tretinoin. In patients who have ATO or tretinoin discontinued for toxicity, gemtuzumab ozogamicin may be given once every 4 to 5 weeks until 28 weeks have elapsed from the CR date. Intrathecal chemotherapy (methotrexate alternating with cytarabine) is recommended in high-risk patients during consolidation.[72]

Maintenance Therapy

Unlike other subtypes of AML, maintenance therapy is an important but controversial component of therapy for APL. Before the development of tretinoin, nonrandomized trials suggested a benefit of continuous low-dose methotrexate and mercaptopurine as maintenance therapy. Larger prospective randomized trials have demonstrated decreased relapse rates in patients who received maintenance therapy (either tretinoin or combination chemotherapy) and some trials have demonstrated increased event-free and overall survival. However, several large APL study (APL0406, UK AML17, and MD Anderson) protocols do not include maintenance therapy for patients in molecular remission at the end of consolidation.[114] The AIDA 0493 study evaluated four maintenance cohorts (intramuscular methotrexate and mercaptopurine, tretinoin, alternating chemotherapy with tretinoin, and observation) and reported a 12-year event-free survival of 69%, with no significant differences between cohorts. Some experts do not recommend the use of maintenance therapy, particularly in low-risk patients.[113,114] NCCN guidelines recommend that APL patients who achieve molecular remission after consolidation should receive maintenance therapy if indicated by treatment protocol.[72]

Relapsed Acute Promyelocytic Leukemia

The overall incidence of relapsed or refractory APL is 5% to 10%, with rates as high as 20% to 30% in high-risk disease. Most relapses occur in the first 3 years following induction therapy. ATO is the agent of choice for relapsed APL, and this agent serves as a backbone for treatment regimens. Multiple studies have reported CR rates of about 80%.[111]

Several regimens consisting of tretinoin, anthracyclines, ATO, high-dose cytarabine, and gemtuzumab ozogamicin are options for relapsed or refractory APL. For patients in early first relapse (<6 months), an anthracycline-based regimen is recommended for those patients with no prior anthracycline. Similarly, ATO should be integrated into the treatment regimen if the patient has not received prior ATO. For patients who relapse (≥6 months) following an ATO-containing regimen, ATO should be continued with tretinoin plus an anthracycline (or single dose of gemtuzumab ozogamicin).

Patients who achieve a hematologic and molecular remission after ATO therapy should proceed to autologous HSCT.[72] Outcomes with autologous HSCT depend on the patient's disease status at the time of transplant. Autologous HSCT in CR2 (vs CR1) is associated with lower overall survival, leukemia-free survival, and increased treatment-related mortality. Autologous HSCT has shown increased disease-free and overall survival as compared to allogeneic HSCT. In patients who present with bone marrow involvement by cytogenetics or molecular testing before transplant, an allogeneic HSCT should be pursued.[72,115]

Patient Monitoring

In comparison to non-APL AML, molecular and cytogenetic testing at the end of remission induction therapy in APL has no prognostic value. Clinicians should therefore not make decisions based on the presence or absence of any genetic abnormalities. Since terminal differentiation of blasts in APL requires more than 40 days, results of a bone marrow biopsy obtained at the end of remission induction can be misleading because insufficient time has elapsed to determine response. Molecular and cytogenetic response assessment should occur after the completion of consolidation treatment.

Detection of residual PML/RARα transcripts in the bone marrow at the end of consolidation therapy is strongly associated with subsequent hematologic relapse. Achievement of PML/RARα-negative status is associated with a higher probability of cure. This molecular technique allows the clinician to assess response to therapy and detect relapse earlier, which might prevent the development of overt disease recurrence and is associated with improved outcomes as compared with delaying treatment until overt morphologic relapse. Most experts recommend that APL patients be routinely evaluated with polymerase chain reaction for PML/RARα every 3 to 6 months for 2 years, and then every 6 months for 2 years.[72]

ROLE OF HEMATOPOIETIC GROWTH FACTORS IN ACUTE MYELOID LEUKEMIA

⑩ Hematopoietic growth factors have been evaluated in AML patients to enhance chemotherapy cytotoxicity, shorten the duration of neutropenia, and reduce the incidence and severity of infection following induction and consolidation chemotherapy. Most studies show limited benefit with the use of colony-stimulating factors as "priming" agents administered during remission induction therapy to recruit leukemia cells into the cycle to enhance susceptibility to cell-cycle–specific chemotherapy agents, leading to increased cell kill. The use of hematopoietic growth factors concurrently during chemotherapy administration is discouraged outside the setting of a clinical trial and is not recommended in the American Society of Clinical Oncology (ASCO) guidelines.[116]

Both filgrastim and sargramostim are FDA approved to prevent neutropenic complications in adult AML patients receiving intensive chemotherapy.

Since myeloid blast cells have receptors for granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, some experts were initially concerned that the use of these factors would stimulate regrowth of leukemia. Although subsequent studies have addressed these concerns, many clinicians do not initiate filgrastim until an initial remission is achieved. Growth factors are not recommended in APL patients during induction therapy because they can increase the risk of differentiation syndrome.[72]

Several randomized trials, primarily in older patients, show that filgrastim or sargramostim reduces the duration of neutropenia following AML-induction chemotherapy. The ASCO Guidelines for the Use of White Blood Cell Growth Factors consider the use of hematopoietic growth factors after initial induction therapy reasonable, with the understanding that the effects on length of hospitalization and incidence of severe infection are modest. Patients older than 55 years derive the greatest benefit, and use is appropriate in this population where more rapid marrow recovery might decrease the duration of hospitalization.[116] Hematopoietic growth factors have been evaluated in patients with AML, including sargramostim, filgrastim, and pegfilgrastim. Although pegfilgrastim is not FDA approved for this indication, evidence supports its use in this setting. Multiple biosimilar products are available. Filgrastim-sndz was the first FDA-approved growth factor indicated in patients with AML receiving induction and consolidation therapy.[117] Filgrastim-aafi was approved to reduce the time of neutrophil recovery and duration of fever in AML patients.[118] The use of hematopoietic growth factors can also interfere with the interpretation of the day 14 bone marrow examination. Hematopoietic growth factors should be discontinued at least seven days before a bone marrow aspirate and biopsy to avoid interfering with the interpretation of the results (ie, may see immature myeloid forms that would suggest residual disease).[72]

SUPPORTIVE CARE

The most common and significant adverse drug reaction of antileukemic agents is marrow suppression. Except for corticosteroids, tretinoin, asparaginase/pegaspargase, and vincristine, antineoplastic agents used to treat acute leukemia cause myelosuppression. During AML remission and postremission therapy, daily monitoring of the complete blood count and the absolute neutrophil count is necessary to determine when red cell and platelet transfusions are needed and when neutropenia occurs and resolves. Marrow hypoplasia from the myelosuppressive regimens usually reaches its lowest point (nadir) after 1 to 2 weeks of therapy and lasts for another 1 to 2 weeks. During this period of hypoplasia, infectious and bleeding complications are major causes of death in leukemic patients.

Since typical signs and symptoms of infection may be absent in the neutropenic host, frequent monitoring of vital signs (particularly fever) and daily assessment are essential. Infection control strategies often include routine handwashing; dietary restrictions; reverse isolation and laminar-air flow rooms; fungal, *Pneumocystis*, and bacterial prophylaxis; and the empiric use of broad-spectrum antibiotics when fever occurs. A joint ASCO/IDSA guideline recommends antibacterial and antifungal prophylaxis in high-risk neutropenic patients (<100 cells/mm^3 [0.1 × 10^9/L] for 7days). Furthermore, *Pneumocystis jirovecii* prophylaxis is recommended in patients receiving chemotherapy associated with >3.5% risk for pneumonia. Leukemia patients who are herpes simplex virus seropositive undergoing induction therapy should receive antiviral prophylaxis.[119,120] See Chapters 144 and 145 for more detailed discussion of infections in immunocompromised patients.

In children, short-term levofloxacin prophylaxis is recommended during intensive chemotherapy for acute leukemias (ie, *de novo* AML, relapsed AML, secondary AML, ambiguous lineage leukemia treated on AML therapy and relapsed ALL) to reduce the risk of bacteremias. However, pediatric HSCT patients have not shown a significant reduction in bacteremia with levofloxacin prophylaxis. Levofloxacin prophylaxis in pediatric leukemia patients decreases the risk of febrile episodes but does not reduce the risk of severe infection or invasive fungal disease.[121] Infectious complications, especially fungi, are a major cause of morbidity and mortality. Therefore, primary antifungal prophylaxis with a mold active agent is strongly recommended for children with AML, undergoing allogeneic HSCT or receiving systemic treatment for GVHD.[122]

Acute leukemia patients, particularly those with an initial elevated WBC count, are at risk for tumor lysis syndrome (see Chapter 150). Measures to prevent the development of urate nephropathy from the rapid destruction of WBCs include allopurinol or rasburicase, and adequate hydration before and during chemotherapy. Rasburicase, a recombinant urate oxidase enzyme produced by genetic modification of *Saccharomyces cerevisiae*, catalyzes the enzymatic oxidation of uric acid into the inactive soluble metabolite, allantoin. In children, rasburicase more rapidly reduces uric acid levels in patients with aggressive malignancies as compared to allopurinol, and reduces the need for dialysis. Rasburicase has been evaluated in adults, and some studies show that fixed dosing produces equivalent outcomes to a weight-based, milligram per kilogram dosing strategy. Due to its high cost, rasburicase is usually limited to patients with ALL who have a high-WBC count or bulky extramedullary disease, aggressive lymphoma, or patients with AML with a high-presenting WBC. Most institutions also include an elevated uric acid as part of the criteria for use. Rasburicase has a rapid onset of action and long duration of action, so many institutions also limit its use to a single dose and allow repeat doses as needed. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency due to an increased risk of methemoglobinemia. Tumor lysis syndrome may result in hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia, and subsequent renal insufficiency.[123]

Hematologic support consists primarily of platelet and packed red blood cell transfusions. Platelet transfusions are often given for peripheral counts below 10,000 cells/mm^3 (10×10^9/L) or clinical signs of bleeding. Transfusions of packed red cells may also be indicated for a hemoglobin less than 8 g/dL (80 g/L; 4.96 mmol/L), fatigue, dyspnea, tachycardia, or chest pain. APL can release procoagulants that can cause disseminated intravascular coagulation, necessitating close monitoring and replacement of coagulation factors with cryoprecipitate.

EVALUATION OF THERAPEUTIC OUTCOMES

The development of a pharmaceutical care plan for a acute leukemia patient begins with information about the patient’s diagnosis and prognosis. Long-term therapeutic goals for the patient may include long-term event-free survival, although palliative care is possible in some patients. The desired short-term outcome is the achievement of remission. Restoration of normal hematopoiesis and a repeat bone marrow biopsy that demonstrates no evidence of disease serve as documentation that remission has been achieved. After the appropriate postremission therapy has been completed, the patient may return monthly for 1 year, and then every 3 months, to check hematologic values. If no evidence of disease exists after 5 years from the diagnosis and the patient has been in continuous CR, the patient is considered cured.

Frequent monitoring of fevers, hematologic and chemistry laboratory values, microbiology reports, and the patient’s physical condition are necessary to identify infection, risk of bleeding, and tumor lysis syndrome early. A coagulation screening panel will identify patients with ongoing disseminated intravascular coagulation, a particular risk with APL.

Clinicians should provide patient education on acute and chronic toxicities of the chemotherapy administered and information regarding antibiotics, antiemetics, nutritional support, hematopoietic growth factors, and other supportive care issues. With the emergence of novel oral agents in the treatment landscape of AML, patients should receive institutional assistance to prevent financial toxicity given potential out-of-pocket expenses that can occur. Financial distress can impact drug therapy adherence, which could potentially impact clinical outcomes. Clinicians need to be actively engaged in assessing drug doses and any dose modifications for organ dysfunction.

Numerous late sequelae from leukemia therapy have been recognized and should be included in the monitoring plan after therapy is completed. Chapter e163 discusses the long-term consequences of HSCT. The Children’s Oncology Group Long-Term Follow-Up Guidelines provide an additional resource for assessment and monitoring.[124]

CONCLUSION

Major scientific discoveries, particularly in the elucidation of molecular and genetic alterations, advanced diagnostic methodologies, and the emergence of novel therapeutics, have improved clinical responses and survival in acute leukemias. In ALL, multiagent chemotherapy with vincristine, corticosteroids, and an anthracycline followed by an allogeneic HSCT remains the standard of care for eligible candidates. Second- and third-generation TKIs in combination with chemotherapy have significantly improved survival in patients with Ph$^+$ ALL. The development of CAR T-cell therapies, in which a patient’s T-cells are genetically programmed to recognize leukemic cells, have offered hope to patients with relapsed or refractory ALL. Childhood ALL requires multiple phases of therapy including CNS prophylaxis and most children treated today are cured of their leukemia. In adult AML, the historical induction therapy “7+3” continues to be used, but the FDA has approved nine new agents since 2017. Next-generation sequencing has identified frequently mutated genes including FLT3, NPM1, DNMT3A, IDH1/2, TET2, and others which are associated with prognosis. Novel therapies such as venetoclax, FLT3 inhibitors, IDH inhibitors, Hedgehog inhibitors, and novel anti-CD33 directed agents are changing the AML treatment landscape.

SELF-ASSESSMENT QUESTIONS

1. TA is a 6-year-old male who presents to the ED with fatigue, easy bruising, and fever. His labs reveal a WBC 62,000 cells/mm^3 (62 × 10^9/L), Hb 7.0 g/dL (70 g/L; 4.34 mmol/L), Hct 21.0%, platelets 26,000/mm^3 (26 × 10^9/L), neutrophils 1%, lymphocytes 69%, monocytes 0%, eosinophils 0%, basophils 0%, blasts 30%. Upon peripheral flow cytometry being performed TA is found to have B-cell acute lymphoblastic leukemia (ALL). His ALL risk classification is considered:

   A. Low risk

   B. Standard risk

   C. High risk

   D. Very high risk

2. CP is a 9-year-old female admitted to the pediatric hematology/oncology floor with concern for leukemia. She has WBC 15,000 cells/mm^3 (15 × 10^9/L) on her CBC. Her bone marrow aspirate shows B-cell ALL. What chemotherapy agent would NOT be a component of her induction therapy for B-cell ALL?

   A. Dexamethasone

   B. Vincristine

   C. Daunorubicin

   D. Pegaspargase

3. AB is a 13-year-old male with newly diagnosed B-cell ALL. Which corticosteroid should be utilized in the treatment regimen for AB?

   A. Prednisone

   B. Dexamethasone

   C. Hydrocortisone

   D. Fludrocortisone

4. LK is an 8-year-old female who is being evaluated on day 32 of induction chemotherapy for B-cell ALL. Her original CBC on admission demonstrated: WBC 40,000 cells/mm^3 (40 × 10^9/L), Hb 6.8 g/dL (68 g/L; 4.22 mmol/L), platelets 26,000 cells/mm^3 (26 × 10^9/L), absolute neutrophil count (ANC) 400 cells/mm^3 (0.4 × 10^9/L), blasts 76%. Her cytogenetics were positive for *CRLF2* gene rearrangement and day 29 bone marrow has 0.5% lymphoblasts. What risk stratification is LK?

   A. Low risk

   B. Standard risk

C. High risk

D. Very high risk

5. Which agent is utilized in the first-line treatment of acute myeloid leukemia (AML)?

A. Blinatumomab

B. Inotuzumab ozogamicin

C. Liposomal combination of daunorubicin and cytarabine (CPX-351)

D. Brexucabtagene autoleucel

6. TS is a 19-year-old male who is to receive tisagenlecleucel for relapsed B-cell acute lymphoblastic leukemia (ALL). Which of the following toxicities is TS most likely to experience?

A. Febrile neutropenia, encephalopathy, hypogammaglobulinemia

B. Cardiotoxicity, pleural effusions, sinusoidal obstruction syndrome

C. Differentiation syndrome, cardiotoxicity, rash

D. Alopecia, cardiotoxicity, tumor lysis syndrome

7. Which of the following karyotypes or molecular mutation profiling represents favorable risk acute myeloid leukemia (AML)?

A. t(8;21) and NPM1 mutation without a FLT3 mutation

B. Normal cytogenetics with FLT3-ITD

C. Complex (≥3 clonal chromosomal abnormalities with a mutated TP53)

D. t(9;11) and core binding factor with KIT mutation

8. DL is a 40-year-old male with newly diagnosed AML. Cytogenetic analysis reveals abnormalities not classified as favorable or poor. He has a mutated NPM1 and FLT3-ITD. What would be the most appropriate induction treatment regimen?

A. Cytarabine 3 g/m^2 IV every 12 hours on days 1, 3, and 5

B. Cytarabine 100 mg/m^2/day continuous IV on days 1 through 7, daunorubicin 60 mg/m^2 IV on days 1 through 3, and midostaurin 50 mg PO daily on days 8 to 21

C. Cytarabine 100 mg/m^2/day continuous IV on days 1 through 7 and daunorubicin 90 mg/m^2 IV on days 1 through 3

D. Venetoclax 400 mg PO daily with low-dose cytarabine 20 mg/m^2 SQ daily on days 1 to 10

9. A 9-year-old female patient of Asian descent with ALL underwent genotyping prior to receiving therapy. The patient was determined to be TPMT (*3A/*3A; poor metabolizer) and NUDT15 (*3/*3; poor metabolizer). Which of the following agents is this patient at increased risk of toxicity for?

A. Brexucabtagene autoleucel

B. Cytarabine

C. 6-Mercaptopurine

D. Methotrexate

10. TC is a 56-year-old male who presents with fatigue and lymphadenopathy. His WBC count is 15,000 cells/mm^3 (15 × 10^9/L), Hb 8.1 g/dL (81 g/L; 5.03 mmol/L), platelets 75,000 cells/mm^3 (75 × 10^9/L), absolute neutrophil count (ANC) 2500 cells/mm^3 (2.5 × 10^9/L), and blasts 15%. The patient is diagnosed with B-cell acute lymphoblastic leukemia (ALL). Cytogenetic analysis reveals t(9:22). His induction chemotherapy treatment regimen should include which of the following?

    A. Cytarabine 100 mg/m^2/day continuous IV on days 1 through 7 and daunorubicin 60 mg/m^2 IV on days 1 through 3

    B. Hyper-CVAD + dasatinib 140 mg/day

    C. Inotuzumab ozogamicin 0.8 mg/m^2 day 1, 8, and 15

    D. Rituximab + dasatinib 140 mg/day

11. Tumor lysis syndrome is characterized by which of the following?

    A. Hypocalcemia, hypouricemia, hyperkalemia

    B. Hyperphosphatemia, hyperkalemia, hyperuricemia

    C. Hypercalcemia, hyperkalemia, hypomagnesium

    D. Hypokalemia, hyperphosphatemia, hypouricemia

12. AB is a 68-year-old female who was diagnosed with AML. Cytogenetic analysis reveals abnormalities not classified as favorable or poor. She has no actionable mutations per molecular testing. The patient has an ECOG performance status of 2 and a recent echocardiogram reveals a left ventricular ejection fraction of 40%. Which of the following is recommended as induction therapy?

    A. Daunorubicin × 3 days, standard dose cytarabine × 7 days

    B. High-dose cytarabine

    C. Liposomal combination of daunorubicin and cytarabine (CPX-351)

    D. Venetoclax + azacitidine

13. RT is a 75-year-old female with significant comorbidities who was diagnosed with AML. Cytogenetic analysis reveals normal cytogenetics and mutational analysis shows wild-type NPM1 without FLT-ITD. What would be the most appropriate induction treatment regimen?

    A. Glasdegib 100 mg PO on days 1 through 28 and cytarabine 20 mg SC twice daily on days 1 and 10

    B. Cytarabine 3 g/m^2 IV every 12 hours on days 1, 3, and 5

    C. Cytarabine 100 mg/m^2/day continuous IV on days 1 through 7 and daunorubicin 45 mg/m^2 IV on days 1 through 3

    D. Gilteritinib 300 mg PO daily

14. Which of the following therapies utilized in the treatment of AML would have a drug interaction with concurrent posaconazole (ie, strong CYP3A4 inhibitor)?

    A. Azacitidine (oral) and venetoclax

    B. Azacitidine (oral) and enasidenib

    C. Enasidenib and glasdegib

    D. Venetoclax and gilteritinib

15. CP is a 59-year-old female is diagnosed with intermediate risk AML (mutated NPM1 and FLT3-ITD). Following standard induction and consolidation therapies, a bone marrow aspirate and biopsy are performed which reveals a complete remission (CR1). Which of the following treatments is recommended now?

    A. Allogeneic transplant if suitable donor identified

    B. Maintenance azacitidine

    C. Maintenance midostaurin

    D. No additional treatment

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** TA is considered high risk due to his WBC (≥50,000/mm^3 (50 × 10^9/L)) at diagnosis. See patient characteristics in the “Acute Lymphoblastic Leukemia” section.

2. **C.** Daunorubicin is used for high-risk ALL induction therapy. CP is considered standard risk until cytogenetics and response to therapy can be assessed. See the “Induction” section for pediatric ALL which discusses that treatment protocols include daunorubicin in induction (four-drug induction) for high-risk or very-high-risk ALL.

3. **A.** Prednisone causes less avascular necrosis in adolescents and young adults. See the “Induction” section for pediatric ALL in which data prednisone and dexamethasone data in standard protocols are discussed.

4. **D.** The patient has *CRLF2* gene rearrangement so she is reassigned to the very-high-risk category which receives the most intensive chemotherapy regimen. See the “Acute Lymphoblastic Leukemia” section for leukemic cell characteristics in which unfavorable or poor prognostic genetic factors such as *CRLF2* rearrangement are discussed.

5. **C.** CPX-351 is indicated to treat newly diagnosed therapy-related AML (t-AML) or AML with myelodysplasia-related changes in adults and pediatric patients aged one year and older. See the “Treatment—Acute Myeloid Leukemia” section.

6. **A.** CAR-T therapies are associated with significant toxicities that include but are not limited to hypogammaglobulinemia, encephalopathy, seizures, and cytokine release syndrome. See the “Relapsed Acute Lymphoblastic Leukemia” section.

7. **A.** Karyotyping and molecular mutational profiling provide important prognostic information in AML. Patients with t(8;21)(q22;q22) and NPM1 mutation without a FLT3 mutation have a favorable prognosis. See the “Risk Classification” section under “Acute Myeloid Leukemia”.

8. **B.** A FLT3 inhibitor such as midostaurin should be integrated into standard induction therapies in patients <60 years old with FLT3/ITD mutations. See the “Treatment—Acute Myeloid Leukemia” section.

9. **C.** Deficiency of TPMT activity or NUDT15 can result in excessive myelosuppression from standard doses of thiopurines. See the “Maintenance Therapy” section.

10. **B.** Adult patients with Ph+ ALL should receive a TKI such as dasatinib incorporated into standard induction therapies such as Hyper-CVAD or CALGB 10701 regimen. The addition of the TKI has improved induction response rates and event-free survival. See the “Acute Lymphoblastic Leukemia in Adults” section.

11. **B.** Electrolyte disturbances commonly seen in TLS include hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia. See the “Supportive Care” section.

12. **D.** Patients who are not candidates for intensive AML induction chemotherapy with no actionable mutations should receive treatment options such as venetoclax + hypomethylating agents (azacitidine, decitabine), low-intensity HMAs, glasdegib + low dose cytarabine, or best supportive care. See the “Treatment—Acute Myeloid Leukemia” section.

13. **A.** Glasdegib is used in combination with low-dose cytarabine for the treatment of newly-diagnosed acute myeloid leukemia (AML) in adults who are 75 years of age or older or who have comorbidities that may preclude the use of intensive chemotherapy. See discussion of the treatment of elderly patients in the “Induction” section under “Treatment Phases.”

14. **D.** Venetoclax has drug interactions with strong or moderate CYP3A4 inhibitors or P-gp inhibitors. Specifically, in the setting of concurrent posaconazole, it is recommended to proceed with initiation and ramp-up dosing starting at 10 mg/day with escalation to 70 mg/day. Concomitant gilteritinib with a combined P-gp and strong CYP3A inducers decreases gilteritinib exposure. It is recommended to consider alternative therapies with strong CYP3A4 inhibitors given the increased risk of adverse drug reactions associated with increased gilteritinib exposure. See Table 4.

15. **A.** The ASTCT recommends allogeneic HSCT for AML patients in CR1 with intermediate- or high-risk disease and CR2 patients. See the “Allogeneic Hematopoietic Stem Cell Transplantation” section.

Chapter 158: Chronic Leukemias

Karen M. Fancher; Jill M. Comeau

KEY CONCEPTS

KEY CONCEPTS

① Chronic myeloid leukemia (CML) is defined by the presence of the Philadelphia chromosome (Ph), a translocation between chromosomes 9 and 22. The resulting abnormal fusion protein, p210 *BCR-ABL*, phosphorylates tyrosine kinase residues and is constitutively active, resulting in uncontrolled hematopoietic cell proliferation.

② Without treatment, the disease course of CML is characterized by a progressive increase in white blood cells over a period of years that ultimately transforms into acute leukemia.

③ Allogeneic hematopoietic stem cell transplant (HSCT) is the only known curative treatment option for CML and is reserved for patients with a suitable donor who progress after treatment with tyrosine kinase-based therapy.

④ The commercially available BCR-ABL tyrosine kinase inhibitors, imatinib, dasatinib, nilotinib, bosutinib, and ponatinib, have demonstrated efficacy in the treatment of newly diagnosed CML patients in chronic phase as well as in patients in accelerated phase or blast crisis.

⑤ CML monitoring requires the assessment of milestones throughout therapy, which includes hematologic, cytogenetic, and most importantly, molecular responses.

⑥ The management of chronic lymphocytic leukemia (CLL) is highly individualized. It includes observation in patients with early-stage disease and treatment with targeted therapy, chemotherapy, and/or biologic therapy in patients with more advanced disease.

⑦ Rituximab, obinutuzumab and ofatumumab are monoclonal antibodies indicated for the treatment of CLL.

⑧ Regimens such as fludarabine, cyclophosphamide, and rituximab are considered first-line therapy for patients with CLL who are younger and have immunoglobulin heavy-chain variable (IGHV) mutation.

⑨ Novel agents such as ibrutinib, acalabrutinib, zanubrutinib, idelalisib, duvelisib, and venetoclax provide orally administered options for the treatment of CLL. These agents, alone or in combination with anti-CD20 monoclonal antibodies, are now preferred treatment options.

This 11-minute video by the Lymphoma Research Foundation briefly reviews CLL, diagnosis, and treatment options. This video is designed to aid in the student's patient care process, particularly the COLLECT and ASSESS steps.

INTRODUCTION

Chronic leukemias include chronic myeloid leukemia (CML), chronic lymphocytic leukemia (CLL), hairy cell leukemia, and prolymphocytic leukemia. The typical clinical presentation of chronic leukemias is an indolent course, in contrast to patients with acute leukemia who will die of their diseases within weeks to months if not treated. This chapter focuses on the two most common types of chronic leukemia, CML and CLL.

CHRONIC MYELOID LEUKEMIA

CML is a myeloproliferative disease that results from malignant transformation of a subpopulation of pluripotent hematopoietic stem cells.[1,2] Bone marrow hyperplasia and the accumulation of differentiated myeloid cells in the peripheral blood are the initial presenting features of the disease. The terminal stage of CML is characterized by the rapid accumulation of blast cells in the bone marrow and suppression of normal hematopoiesis that ultimately leads to death. CML was the first malignant disease identified with a consistent cytogenetic abnormality, namely the Philadelphia Chromosome (Ph) that contains the BCR-ABL oncogene. This dominant cytogenetic abnormality has allowed CML to become the template for the development of targeted drug therapies.[2]

Epidemiology and Etiology

It is estimated that 8,860 new cases of CML will be diagnosed in the United States in 2022.[3] The median age at diagnosis is 67 years.[4] The development of CML is not associated with hereditary, familial, geographic, ethnic, or economic status. An increased risk of CML has been noted with ionizing radiation exposure and in atomic bomb survivors from Hiroshima and Nagasaki.[2]

Pathophysiology

CML was first described in 1845, but extensive research into the genetic and molecular characteristics of the disease began with the discovery of the Ph in 1960 by Nowell and Hungerford.[5] Research in the 1980s identified the molecular changes that occur as a result of the Ph when an oncogenic protein was identified and associated with the pathophysiology of CML.[1,5] Ph is the first karyotypic abnormality specifically implicated in the pathogenesis of cancer, and its discovery has resulted in extensive research into the molecular biology of CML. This chromosomal abnormality is characteristic of CML and is present in about 95% of patients with the disease.[1]

① Ph, identified as a shortened long arm of chromosome 22, is found in granulocyte and erythrocyte progenitors, macrophages, megakaryocytes, and lymphocytes. The Ph is the consequence of breaks in chromosomes 9 and 22, resulting in a transposition that relocates the 3′ end of *ABL* (Abelson proto-oncogene) from its normal site on chromosome 9 at band 34 to the 5′ end of *BCR* (breakpoint cluster region) on chromosome 22 at band 11 (symbolized as *t*[9;22][q34;q11]).[1,6] This results in the formation of the hybrid *BCR-ABL* fusion gene (Fig. 158-1). Through this chromosomal translocation, the *ABL* proto-oncogene escapes normal genetic controls and is activated into a functional oncogene, directing the transcription of messenger ribonucleic acid (mRNA). The mRNA is translated into a 210-kDa protein—p210 BCR-ABL—that is constitutively (ie, constantly) activated compared to the 145-kDa protein translated by the normal *ABL* gene.[1,6]

FIGURE 158-1

Specific chromosomal translocation that results in the Philadelphia chromosome. The fusion of these DNA sequences allows the generation of a constitutively activated fusion protein. *(Reproduced, with permission, from Jameson JL, Fauci AS, Kasper DL, Hauser SL, Longo DL, Loscalzo J, eds. Harrison's Principles of Internal Medicine. 20th ed. New York, NY: McGraw Hill; 2019.)*

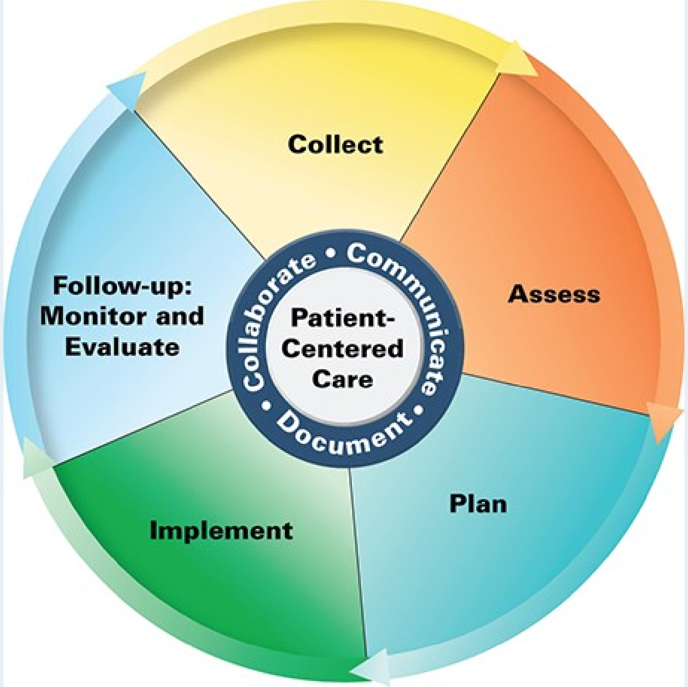
CML is considered a clonal disease because it begins with the malignant transformation of a single cell. The progeny from this transformed primitive hematopoietic stem cell results in a proliferative advantage over normal hematopoietic cells that displaces normal hematopoiesis. The Ph is found in both myeloid and lymphoid cells, which suggests that the transformed cell of CML is a pluripotent stem cell.[2] Disrupted maturation leads to a number of circulating granulocytes that may be many times higher than normal. In the advanced stages of CML, cytopenias may occur in association with fibrotic changes in the bone marrow.

The *BCR-ABL* fusion gene encodes for a constitutively active tyrosine kinase that is involved in both the increased proliferation of the CML clone and a reduction in apoptosis.[7] Characterization of the adenosine triphosphate binding site on the BCR-ABL tyrosine kinase has provided a target for inhibition of tyrosine kinase activity. The first Food and Drug Administration (FDA)-approved tyrosine kinase inhibitor (TKI), imatinib mesylate (Gleevec®), was indicated for patients in chronic phase who had failed interferon alfa (IFN-α) or for those with advanced disease. Imatinib received additional FDA approval in 2002 for first-line treatment in newly diagnosed CML. Second-generation TKIs with a higher binding affinity and selectivity for BCR-ABL kinase are now approved as both first-line agents and salvage therapy for patients with resistance or intolerance to imatinib.

Patient Care Process

Patient Care Process for Chronic Myeloid Leukemia (CML)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex)
- Patient medical history (personal and family)
- Social history (eg, tobacco/ethanol use)
- Current medications including acid-suppressing agents, herbal products, dietary supplements, and inhibitors/inducers of CYP3A4
- Objective data
  - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
  - Labs including Complete Blood Counts (CBC) with differential, comprehensive metabolic panel, liver function tests and uric acid
  - Objective confirmation of CML via bone marrow biopsy with chromosomal and molecular analysis

Assess

- Bone marrow biopsy morphology, cytogenetics, molecular mRNA transcripts
- CBC and presence of active bleeding due to potential thrombocytopenia
- Presence of VTE provoking factors (eg, recent surgery, plaster casting of lower extremity, indwelling catheter)
- Ability/willingness to obtain laboratory monitoring tests (eg, CBC, CMP, BCR-ABL assessments)
- Comorbidities (eg, diabetes, chronic kidney disease, pulmonary arterial hypertension)
- Emotional status (eg, presence of anxiety, depression)

Plan

- Drug therapy regimen including tyrosine kinase inhibitor dose, route, frequency, and duration (see Tables 158-3 and 158-4)

- Monitoring parameters including efficacy (eg, cytogenetic response, BCR-ABL mRNA PCR) and safety (eg, sign and symptoms of bleeding, anemia, fluid retention, ECG); frequency and timing of follow-up
- Patient education (eg, goal of treatment, drug-specific information, oral medication adherence, drug–drug interaction)

Implement

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence to oral therapy

Follow-up: Monitor and Evaluate

- Routinely monitor for assessment of hematologic, cytogenetic, and molecular milestones
- Presence of adverse drug reactions
- Patient adherence to treatment plan using multiple sources of information
- Addition of any new medications, including over-the-counter agents and/or herbal supplements

***Collaborate with patient, caregivers, and other healthcare professionals.*

Clinical Presentation

The diagnosis of CML is often made incidentally during a routine examination or when a complete blood count is obtained for unrelated reasons, as patients are often asymptomatic upon presentation. The differential diagnosis of CML includes infection, myeloproliferative disorders (ie, polycythemia vera, essential thrombocythemia, myelofibrosis), and chronic myelomonocytic leukemia. Initial laboratory workup includes complete blood count with differential and complete metabolic panel. A bone marrow aspiration and biopsy are required to confirm the diagnosis of CML.[6] Bone marrow is markedly hypercellular (75%-90%) with increased erythropoiesis and normal megakaryocytes.[4,6] Karyotyping (ie, cytogenetic analysis) is required for a diagnosis. The bone marrow aspiration is analyzed with fluorescence in situ hybridization (FISH) to determine the presence of the Ph chromosome. Quantitative reverse-transcription polymerase chain reaction (RT-PCR) is also performed to assess the baseline *BCR-ABL* transcript levels in the blood and monitored with the International Scale (IS). In the IS, the standardized baseline, defined as the mean expression of *BCR-ABL1* transcripts observed from previous study patients, is set to 100%. Levels measured by individual laboratories may need to be converted to the IS by a conversion factor.

② Historically, the three clinical phases of CML were chronic phase (CP), accelerated phase (AP), and blast crisis (BC) (Table 158-1).[4,6] Newer classification systems now classify CML into two clinical phases: chronic phase and advanced phase (AP).[6] Although many patients in CP-CML are asymptomatic, signs and symptoms may include fatigue, sweating, bone pain, weight loss, abdominal discomfort, and early satiety secondary to splenomegaly.[8] Leukocytosis is the hallmark of CP, and the white blood cell count can be as high as 1,000,000 cells/mm^3 (1,000 × 10^9/L), placing patients at risk for complications of leukostasis. Symptoms secondary to leukostasis include acute abdominal pain resulting from splenic infarctions, priapism, retinal hemorrhage, cerebrovascular accidents, confusion, hyperuricemia, and gouty arthritis.

TABLE 158-1

Criteria for Different Phases of Chronic Myeloid Leukemia

Chronic Phase	Accelerated Phase	Blast Crisis
• <10% blasts in peripheral blood or bone marrow	• 10%-19% blasts in peripheral blood or bone marrow • Platelets <100,000 cells/mm^3 (100 × 10^9/L) unrelated to therapy or >1,000,000 cells/mm^3 (1,000 × 10^9/L) unresponsive to therapy • Persistent or increasing white blood cells >10,000 cells/mm^3 (10 × 10^9/L), unresponsive to therapy • 20% or more basophils in the peripheral blood • Any new clonal chromosomal abnormalities in Ph+ cells that occur during therapy	• >20% blasts in peripheral blood or bone marrow • Large clusters of blasts on bone marrow biopsy • Presence of extramedullary infiltrates
	Additional findings • Cytogenetic evolution • Progressive splenomegaly, unresponsive to therapy	

Data from References 6,10,11.

AP is characterized by a loss of efficacy of drug therapy and the progressive arrest of myeloid maturation. The most commonly observed cytogenetic changes with disease progression are an additional Ph chromosome, trisomy 8, trisomy 19, and isochromosome 17q.[8,11]

BC is the terminal stage of the disease and clinically resembles acute leukemia, in which the leukemic clone overwhelmingly dominates the bone marrow at the expense of normal hematopoiesis. The WHO classification defines BC CML as the presence of one or more of the following: greater than 20% blasts in the peripheral blood or bone marrow, extramedullary disease, or large clusters of blasts in the bone marrow.[6,9] Patients can present occasionally with BC without an apparent AP. One-third of patients present with BC of lymphoid lineage, while two-thirds present with BC of myeloid lineage or undifferentiated phenotype. The transformation to BC CML is the consequence of several factors in addition to *BCR-ABL*, such as the activation of the oncogene signaling pathways and loss of tumor suppressors such as p53.

CLINICAL PRESENTATION: Chronic Myeloid Leukemia

General

- 90% of patients are diagnosed in CP
- 50% are asymptomatic in CP and often diagnosed following abnormal complete blood count

Signs and Symptoms

- Fatigue
- Left upper quadrant pain
- Abdominal pain or distension
- Weight loss
- Night sweats

Physical Examination

- Splenomegaly
- Hepatomegaly

Laboratory Tests

Peripheral blood

- Leukocytosis
- Thrombocytosis
- Basophilia
- Low or undetectable leukocyte alkaline phosphatase
- Elevated uric acid and lactate dehydrogenase

Molecular testing

- Presence of *BCR-ABL* by RT-PCR

Bone marrow

- Hypercellular
- Fully mature myeloid cells
- Increased megakaryocytes
- <10% blasts in CP

Cytogenetics

- Presence of Ph
- Additional abnormalities may occur

Data from References 4,6.

Prognosis

Several models have been proposed to estimate prognosis in patients with CML, but the model developed by Sokal et al. is the historical standard.[12] The Sokal algorithm uses spleen size, percentage of circulating blasts, platelet count, and age as prognostic factors for patients in CP. However, this scoring system was developed before the advent of TKI therapy and may have limited predictive value in the current treatment landscape. The median overall survival for patients diagnosed with CP, AP, and BC CML was reported to be 47 months, 12 to 24 months, and 3 to 6 months, respectively, in the era before TKIs were introduced.[13]

The European Treatment and Outcome Study (EUTOS) Long Term Survival (ELTS) score is gaining popularity since it is based on data from patients with CML treated with TKIs.[6,14] Factors such as age, spleen size, platelet count and percentage of circulating blasts are used to stratify patients into low, intermediate or high risk of disease progression.

Treatment: Chronic Myeloid Leukemia

Desired Outcomes

Without effective treatment, CML disease progression leads inexorably to a fatal outcome within 5 years. The introduction of TKI therapy has dramatically altered the clinical course of CML, as patients can now expect to maintain disease control for many years.[4] The survival of patients who are newly diagnosed with CML in CP is now nearly equivalent to that of the general population, with the risk of death from other comorbid conditions greater than from CML.[4,6,15]

The overriding treatment goals for CML include the eradication of the leukemic clone from the bone marrow and maintenance of CP with minimal toxicity from treatment.[4,6] The only proven therapy to eradicate the malignant clone from the bone marrow is allogeneic hematopoietic stem cell transplantation (HSCT). Both immunotherapy with IFN-α and TKI-based therapies have demonstrated the ability to extend CP beyond the expected period of several years, with TKIs now being the preferred treatment option.[4,6]

Clinical response in CML is measured by hematologic, cytogenetic, and molecular indices, all of which have standardized criteria.[1,4,16] *Hematologic response* is defined as the normalization of peripheral blood counts and is the earliest type of response observed in CML patients. *Cytogenetic responses* are based on the percentage of cells positive for Ph in a bone marrow biopsy. A *complete cytogenetic response* is defined as the elimination of Ph from all cells in the marrow sample and a *major cytogenetic response* is defined as ≤35% Ph-positive cells. Patients who have a major or complete cytogenetic response have improved survival compared to those who fail to achieve a cytogenetic response.

More sensitive and less invasive tests to monitor disease status are now used because most patients on BCR-ABL TKIs achieve a complete cytogenetic response.[4] *Molecular responses* are determined by RT-PCR (based on IS), which are several logs more sensitive than methods used to measure cytogenetic responses. An early molecular response is the observation of ≤10% *BCR-ABL* (IS) at 3 and 6 months. A *major molecular response* is a ≥3 log reduction in *BCR-ABL* mRNA from the baseline or a BCR-ABL (IS) of <0.1%. A *complete molecular response* is the absence of *BCR-ABL* transcripts by RT-PCR. Clinicians should interpret RT-PCR assays carefully because they have varying sensitivities and may show a complete molecular remission even when low levels of *BCR-ABL* transcripts are present.[17] Quantitative RT-PCR should be performed before initiating therapy and throughout therapy to monitor residual disease. Peripheral blood can often be used for this analysis because bone marrow and peripheral blood *BCR-ABL* mRNA levels are correlated.

Hematopoietic Stem Cell Transplantation

③ The advent of TKI therapy has resulted in fewer transplants for patients with CML. Allogeneic HSCT remains the only proven therapy to cure patients with CML, with many patients alive and disease-free decades after transplant. Patients undergoing allogeneic HSCT from a human leukocyte antigen (HLA)-matched sibling donor have 5-year survival rates ranging from 60% to 80% and long-term survival of about 50%.[17] In most long-term survivors, the *BCR-ABL* translocation is absent in all diagnostic tests including RT-PCR. Prognostic risk factors associated with survival outcomes include age, phase of disease, and disease duration.[4,6] Increased age is associated with a poorer prognosis, with higher transplant-related mortality in patients older than age 50 years. Patients with CP who receive allogeneic HSCT have better outcomes than those in AP or BC at the time of transplant. The time from diagnosis to transplantation also affects outcomes. Patients who undergo matched-sibling allogeneic HSCT within the first year of diagnosis have a better 5-year survival rate than those who undergo transplantation more than 1 year after their diagnosis (70-80% vs 50-60%).[17] However, these data were reported prior to the use of imatinib as first-line therapy for CML.

The major limitation for the application of HSCT is that fewer than 30% of transplant-eligible patients will have an HLA-matched sibling donor. The most practical approach is to use an HLA-matched unrelated donor, if a HLA-matched sibling donor is not available. Matched unrelated donor HSCT has an overall 5-year survival reported to be 40% to 70%, which approaches overall survival data results reported for matched-sibling donor HSCT.[17] Imatinib use before transplantation does not appear to adversely affect transplant-related mortality.[18]

Treatment options in patients who relapse after HSCT are limited. Graft-versus-leukemia (GVL) effect, TKIs, omacetaxine, IFN-α, or a clinical trial are reasonable options.[6] The infusion of donor lymphocytes functions as a form of adoptive immunotherapy that can induce a GVL effect. In relapsed CML, donor lymphocytes induce durable responses and these responses strongly correlate with the development of graft-versus-host disease (GVHD).[6,19]

Conventional Chemotherapy

At present, conventional cytotoxic chemotherapy is only used in CML to reduce and temporarily control high peripheral white blood cell (WBC) counts. The agent most often used for cytoreduction is hydroxyurea (Hydrea®).[20] Hydroxyurea rapidly lowers high circulating WBCs in CML by inhibiting ribonucleotide reductase, which inhibits DNA synthesis, eliminating cells in the S phase of the cell cycle, and synchronizing cells in the G_1 or pre-DNA synthesis phase. Hydroxyurea is initiated at 40 to 50 mg/kg/day in divided doses until the WBC count falls to approximately 10,000 cells/mm^3 (10×10^9/L). Hydroxyurea may be discontinued once adequate control of the WBC count is achieved and a TKI has been initiated. Hydroxyurea does not change the natural progression of the disease to BC.

Interferon Alfa

The interferons are a family of glycoproteins involved in many of the functional aspects of the hematopoietic system. Before imatinib was available, IFN-α was the preferred agent in the treatment of CML. The use of IFN-α in the treatment of CP CML was based on reports that 20% to 50% of patients achieved a major cytogenetic response, which led to prolonged survival.[1,21] However, IFN-α use is limited by its toxicity profile, as it is associated with both short-term constitutional toxicities and potentially dose-limiting long-term toxicities.[1,22,23] The most predictable early toxicity is a flu-like syndrome characterized by fever, chills, myalgia, headache, and anorexia. These dose-dependent effects may be a result of IFN-α–induced leukocytosis and the release of inflammatory cytokines. Cardiovascular toxicities (eg, tachycardia, hypotension) are seen in about 15% of patients in the first few weeks. Long-term adverse drug reactions include weight loss, alopecia, neurologic effects (eg, paresthesia, cognitive impairment, and depression), and immune-mediated complications (eg, hemolysis, thrombocytopenia, nephrotic syndrome, systemic lupus erythematosus, and hypothyroidism), which occur in about 5% to 20% of patients. The National Comprehensive Cancer Network (NCCN) guidelines now recommend IFN-α only for CML patients with post-transplant relapse or during pregnancy if the treatment benefit outweighs the risk to the mother and fetus.[6]

Tyrosine Kinase Inhibitors

④ A transformative discovery in cancer therapeutics was the characterization of the adenosine triphosphate binding site on the BCR-ABL tyrosine kinase. This specific receptor established a novel drug discovery platform for molecularly targeted therapy in CML. Numerous TKIs were in development in the 1990s and STI571 (STI stands for *signal transduction inhibitor*), subsequently named imatinib, has high binding affinity for the BCR-ABL tyrosine kinase and emerged as the drug with the best oral bioavailability at that time.[24] Imatinib competitively binds to the adenosine triphosphate (ATP)-binding site on BCR-ABL, which inhibits the phosphorylation of proteins involved with CML clone proliferation. In 2001, imatinib mesylate received FDA approval for patients in CP-CML who had failed IFN-α treatment and in patients with AP- or BC-CML based on phase II studies. In 2002, it received FDA approval for first-line treatment in newly diagnosed CML based on the IRIS phase III trial results.[22] Imatinib inhibits several other tyrosine kinases including BCR-ABL, c-Kit, and platelet-derived growth factor receptor (PDGFR) (Table 158-2).[22]

TABLE 158-2

Cytogenetic and Molecular Response Rate Associated with Tyrosine Kinase Inhibitor Therapy in Chronic Myeloid Leukemia

Drug (Disease Status)	Daily Dose (mg)	CCyR (%)	MMR	Median Follow-up (months)
Imatinib (CP)	400	82	57%	70
	800	90	NR	30
Imatinib (AP)	600	43	NR	12
	400	11	NR	
Imatinib (BC)	400-800	7.40	NR	—
Dasatinib (CP)	100	83	76%	60
Dasatinib (AP)	140	32	NR	15
Nilotinib (CP)	600	87	77%	36
Nilotinib (AP)	800	16	NR	24
Bosutinib (CP–3rd line)	500	24	15%	28.5
Bosutinib (CP–1st line)	500	79	59%	12
Omacetaxine (CP–2nd line, T315I mutation)	2.5	16	NR	19.1
Ponatinib (CP-resistant/intolerant disease)	45	37	NR	10
Ponatinib (CP-T315I mutation)	45	66	NR	10

AP, accelerated phase; BC, blast crisis; CCyR, complete cytogenetic response; CP, chronic phase; MCyR, major cytogenetic response; MMR, major molecular response; NR, no response.

Table 158-3 summarizes the dosing, food–drug interactions, and drug–drug interactions of imatinib and other TKIs.

TABLE 158-3

Dosing of Tyrosine Kinase Inhibitors in Chronic Myeloid Leukemia*

Drug	Brand Name	Dose Range	Food–Drug Interactions	Drug–Drug Interactions
Imatinib	Gleevec®	• 400 mg/day (CP) • 600 mg/day (AP/BC)	Take with food and a large glass of water	• CYP3A4 inducers may decrease C_{max} and AUC • CYP3A4 inhibitors may increase C_{max} and AUC • Imatinib inhibits CYP3A4 and 2D6 • Package labeling recommendations against using warfarin concurrently
Dasatinib	Sprycel®	• 100 mg/day (CP) • 140 mg/day (AP/BC)	With or without meals; do not crush tablets	• CYP3A4 inhibitors may increase dasatinib levels • CYP3A4 inducers may decrease dasatinib levels • H_2 antagonists/PPIs decrease dasatinib levels
Nilotinib	Tasigna®	• 300 mg BID (CP) • 400 mg BID (AP/BC)	Take with water; avoid food 2 hours prior to a dose or 1 hour after	• Avoid drugs concurrently known to prolong QT interval • CYP inducers may decrease nilotinib concentrations • CYP inhibitors may increase nilotinib concentrations • H_2 antagonists/PPIs decrease nilotinib levels • Nilotinib is an inhibitor of CYP3A4, CYP2C8, CYP2C9, and CYP2D6 • Nilotinib is an inducer of CYP2B6, CYP2C8, and CYP2C9
Bosutinib	Bosulif®	• 400 mg/day (CP) • 500 mg/day (AP/BC or resistance/intolerance to other TKI therapy)	Take with food; PPIs may decrease absorption	• Concurrent use with CYP3A4 or Pgp inhibitors increase bosutinib concentrations • Concurrent use with CYP3A4 inducers reduces bosutinib concentrations
Ponatinib	Iclusig®	45 mg/day (lower dosing may be required as the optimal dose is not defined)	With or without food	• Concurrent use with CYP3A4 or Pgp inhibitors increase ponatinib concentrations • Concurrent use with CYP3A4 inducers reduces ponatinib concentrations

AP, accelerated phase; AUC, area under the curve; BC, blast crisis; BID, twice daily; Cmax, maximum concentration; CP, chronic phase; CYP, cytochrome P450; Pgp, P-glycoprotein; PPI, proton pump inhibitor.

[*] *Information obtained from each agent's prescribing information.*

Adverse Drug Reactions and Drug Interactions

Tables 158-3 and 158-4 summarize drug–drug interactions, adverse drug reactions, and monitoring of BCR-ABL TKIs.

Monitoring of Tyrosine Kinase Inhibitors in Chronic Myeloid Leukemia[*]

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Imatinib	Common: ○ Myelosuppression ○ Fluid retention (pleural/pericardial effusion, ascites, periorbital, and peripheral edema) ○ Nausea/vomiting ○ Rash ○ Fatigue ○ Hepatotoxicity ○ Hypothyroidism ○ Myalgias Rare but serious: ○ Congestive heart failure/left ventricular dysfunction ○ Hemorrhage ○ Bullous dermatologic reactions	● CBC for myelosuppression ● CMP for hepatotoxicity ● Consider baseline echocardiogram if preexisting cardiac dysfunction or risk factors for cardiac dysfunction, repeat if experiencing symptoms of cardiac dysfunction ● Thyroid-stimulating hormone	Nausea and vomiting improved when administered with food
Dasatinib	Common: ○ Myelosuppression ○ Myalgia ○ Fluid retention ○ Cardiotoxicity ○ Rash ○ Gastrointestinal toxicity ○ Hypophosphatemia ○ Hepatotoxicity Rare but serious: ○ Pleural effusion ○ Pericardial effusion ○ QT prolongation	● CBC for myelosuppression ● CMP for hypophosphatemia and hepatotoxicity ● ECG if risk factors for QTc prolongation ● Chest radiograph for signs and symptoms of pleural effusion ● Evaluate for signs/symptoms of underlying cardiopulmonary disease for pulmonary arterial hypertension	Gastrointestinal hemorrhage reported to be fatal; severe pleural effusions requiring thoracentesis; fatal myocardial infarction are reported

	○ Congestive heart failure/left ventricular dysfunction ○ Pulmonary arterial hypertension ○ Hemorrhage		
Nilotinib	Common: ○ Myelosuppression ○ Rash ○ Gastrointestinal toxicity ○ Peripheral edema ○ Liver function abnormalities ○ Elevated serum lipase/amylase ○ Electrolyte abnormalities (hypophosphatemia, hypokalemia, hypocalcemia, and hyponatremia) Rare but serious: ○ Tumor lysis syndrome ○ Cardiotoxicity (QTc prolongation/sudden cardiac death/left ventricular dysfunction)	• CBC for myelosuppression • CMP for hypophosphatemia and hepatotoxicity • Serum amylase/lipase • Lipid panel • ECG if risk factors for QTc prolongation at baseline, 7 days thereafter and then as clinically indicated	Sudden deaths reported with nilotinib; ventricular repolarization abnormalities may have been contributory
Bosutinib	Common: ○ Myelosuppression ○ Gastrointestinal toxicity ○ Fluid retention ○ Hepatotoxicity ○ Hypophosphatemia ○ Rash Rare but serious: ○ Embryofetal toxicity	• CBC for myelosuppression • CMP for hypophosphatemia and hepatotoxicity • Serum amylase/lipase • ECG if risk factors for QTc prolongation at baseline, 7 days thereafter and then as clinically indicated	Potential for additive risk of hepatotoxicity when given concurrently with letrozole
Ponatinib	Common: ○ Myelosuppression ○ Arthralgia ○ Headache ○ Fatigue ○ Fever	• CBC for myelosuppression • Serum lipase • CMP for hepatotoxicity, at baseline for tumor lysis syndrome • Blood pressure as clinically indicated • Ocular exam at baseline and then as clinically	Deaths reported from hepatotoxicity, thrombosis including myocardial infarction and hemorrhage

	◦ Pancreatitis ◦ Elevated lipase ◦ Hypertension ◦ Gastrointestinal toxicity ◦ Dermatologic toxicity ◦ Electrolyte abnormalities ◦ Fluid retention Rare but serious: ◦ Arterial thrombosis ◦ Hepatotoxicity ◦ Cardiotoxicity (arrhythmia/congestive heart failure) ◦ Embryofetal toxicity ◦ Hemorrhage ◦ Tumor lysis syndrome ◦ Impaired wound healing/GI perforation ◦ Ocular toxicity	indicated	

CBC, complete blood count; CMP, comprehensive metabolic panel; ECG, electrocardiogram; GI, gastrointestinal.

Information obtained from each agent's prescribing information.

Myelosuppression is one of the most common adverse drug reactions observed during therapy with imatinib.[25] Moderate-to-severe myelosuppression occurs in about 5% to 10% of patients with CP-CML and 50% to 60% of patients in AP or BC. Myelosuppression typically occurs within the first 4 weeks of therapy and is more common in patients with advanced disease (ie, high blastic involvement of the bone marrow), those receiving higher doses and those with low hemoglobin. When imatinib is initiated, patients should have complete blood counts drawn every 1 to 2 weeks to assess for myelosuppression until they have stabilized.[26] Appropriate initial management of myelosuppression is to interrupt imatinib treatment rather than dose reduce because dose reductions below 300 mg daily do not fully inhibit BCR-ABL and may lead to the emergence of imatinib resistance.[4,6]

Many other non-hematologic toxicities associated with imatinib have been reported (Table 158-4).[4,6,26] Drug rash frequently occurs but is usually mild and can be managed with antihistamines or topical steroids. Hepatotoxicity can occur with imatinib, and the drug should be withheld if liver function tests exceed five times the upper limits of normal. It is recommended that patients on imatinib limit their use of acetaminophen to 1,300 mg daily.[6] Other medications that are known to be hepatotoxic should be used with caution while patients are treated with imatinib.

Dasatinib can cause edema and pleural effusions, which can be managed by drug holiday, diuretics, thoracentesis, and/or short courses of steroids.[4,6,26,27] Dasatinib may also be associated with an increased risk of bleeding due to its effects on PDGFR.[28] A rare adverse drug reaction of dasatinib is pulmonary arterial hypertension (PAH), which warrants permanent discontinuation.[6,27] Nilotinib can be associated with indirect bilirubin elevations in 10% to 15% of patients.[4,6,26,27] Nilotinib may prolong the QTc interval (Black Box Warning), and patients should have an electrocardiogram at baseline, at 7 days following initiation of therapy, and periodically thereafter. Nilotinib has also been associated with "metabolic syndrome," consisting of hyperglycemia, hypercholesterolemia and hypertriglyceridemia; careful attention should be given to eliminate or reduce risk factors for these conditions. Bosutinib is associated with gastrointestinal adverse drug reactions such as diarrhea, nausea and vomiting, and abdominal discomfort.[4,6,26] These gastrointestinal effects are typically self-limiting and can be managed with over-the-counter medications. Ponatinib can cause hepatotoxicity (including reports of liver failure), vascular occlusion, and heart failure, with some events occurring within 1 week of starting therapy.[4,6,27,29] The ponatinib manufacturer recommends specific dose modifications for myelosuppression, hepatotoxicity, and elevated lipase; monitoring for cardiovascular effects should also be routinely performed.

Similar to imatinib, advanced-generation TKIs are metabolized by cytochrome P450 (CYP) 3A4.[30] Clinicians need to be aware of possible drug interactions with inducers and inhibitors of the CYP3A4 pathway such as phenytoin, azole antifungals, or macrolide antibiotics (Table 158-3).[6,26] Drug interactions with BCR-ABL can not only affect toxicity but efficacy outcomes as well. It is recommended to re-evaluate drug–drug and, if applicable, drug–food interactions in patients do not reach their disease response goal.

Similar to other chronic medications, adherence should be reinforced in patients taking BCR-ABL TKIs.[4,6,26,31] Potential barriers to adherence, such as cost, adverse drug reactions, and frequency of dosing, should be identified and routinely assessed. An observational study, ADAGIO, evaluated 169 patients receiving imatinib and found that only 67% of patients were adherent. The percent of imatinib not taken was associated with a lower rate of complete cytogenetic response.[32]

Treatment of Chronic Phase

The IRIS study compared imatinib 400 mg orally daily to IFN-α plus low-dose subcutaneous cytarabine in 1,106 patients with newly diagnosed CP-CML.[22] After a median follow-up of 19 months, patients who received imatinib achieved a complete hematologic response of 95%, major cytogenetic response of 85%, and complete cytogenetic response of 76%. Six percent of patients had progressed to AP or BC, and only four patients discontinued imatinib because of an adverse drug reaction. After 5 years of follow-up, only 3% of patients randomized to receive IFN-α remained on this agent compared to 69% of patients in the imatinib arm.[33] The estimated 10-year overall survival of the 553 patients originally randomized to receive imatinib is 83.3%, with 47% alive and still on initial imatinib treatment. At 10 years, the estimated event-free survival was 79.6%.[34]

Higher doses of imatinib have been evaluated in clinical trials. The German CML IV study randomized 1,551 patients with CP-CML to 400 mg or 800 mg of imatinib daily in a phase III trial.[35,36] Patients who received 800 mg daily were significantly more likely to achieve a major molecular response at 12 months than patients who received 400 mg daily. However, there was no difference between the treatment groups in progression-free or overall survival at 3 or 10 years. Higher doses of imatinib were associated with higher rates of dose interruption, reduction and discontinuation. The results of this study and others do not justify the routine use of imatinib 800 mg daily as first-line therapy in patients with CML.[6,35–37]

Dasatinib (Sprycel®), nilotinib (Tasigna®) and bosutinib (Bosulif®) are second-generation TKIs originally used for the treatment of CML in patients who are resistant or intolerant to imatinib therapy; all three drugs are also approved for first-line treatment of CP CML. The encouraging results of phase III trials of these agents make them viable alternatives to imatinib for first-line treatment for newly diagnosed CP-CML.[6]

Dasatinib is an oral BCR-ABL TKI that was FDA approved in 2006 to treat imatinib-resistant CML. Dasatinib is also a TKI of the SRC family, c-KIT, EPHA2, and PDGFR.[28] Preclinical data show that dasatinib is approximately 300 times more potent than imatinib and inhibits the growth of imatinib-resistant clones, except for the T315I mutation. Dasatinib has been evaluated as first-line therapy in the phase III DASISION trial, which included 519 patients with CP-CML.[38] Patients were randomized to dasatinib 100 mg once daily or imatinib 400 mg once daily. A greater percentage of patients achieved a complete cytogenetic response at 12 months with dasatinib compared to imatinib (83% vs 72%). The rate of complete cytogenetic response at 5 years was higher with dasatinib as compared to imatinib (83% vs 78%).[39] The rate of major molecular response was significantly higher in the dasatinib group (76% vs 64%). Five-year progression-free and overall survival were similar in the two groups. A trial evaluating different dosing strategies of dasatinib showed that 100 mg once daily was as efficacious as dasatinib 70 mg twice daily, 50 mg twice daily or 140 mg once daily but with decreased adverse drug reactions such as pleural effusions.[40] The standard dose of dasatinib for patients with CP-CML is now accepted to be 100 mg daily.

Nilotinib has 20 to 30 times the inhibitory activity of the BCR-ABL tyrosine kinase than imatinib, with activity against c-Kit and PDGFR (but not SRC kinases) due to a modification of the methylpiperazinyl structure of imatinib.[28] Nilotinib has inhibitory activity against imatinib-resistant mutants, with the exception of T315I. For first-line treatment of CP-CML, results of the phase III randomized ENESTnd trial comparing nilotinib at two doses (300 or 400 mg twice daily) to imatinib 400 mg once daily in 846 patients has been published.[41] The primary end point of the trial was major molecular response. In the final 5 year analysis, both nilotinib arms had a significantly higher major molecular response rate at 12 months (77% for nilotinib 300 and 400 mg twice daily) as compared to imatinib (60%).[42] The nilotinib arms also had significantly improved time-to-progression to AP or BC, as compared to the imatinib arm. The number of patients who discontinued treatment was similar in the three treatment arms.

Bosutinib has 15 to 100 times the inhibitory activity of the BCR-ABL tyrosine kinase as imatinib, with activity against SRC kinases but minimal activity against c-Kit and PDGFR.[28] Bosutinib has demonstrated clinical activity against many BCR-ABL kinase domain mutations that are resistant to imatinib, dasatinib, and nilotinib, with T315I as the notable exception. The phase III BELA trial of bosutinib 500 mg daily compared to imatinib 400 mg daily in CP-CML did not meet its primary endpoint of complete cytogenetic response at 12 months, likely as a result of a premature discontinuation rate in the bosutinib arm due to gastrointestinal toxicities.[43] A second phase III trial entitled BFORE compared bosutinib at a lower dose of 400 mg daily to imatinib 400 mg daily in 536 CP-CML patients.[44] Patients who received bosutinib had significantly higher rates of both major molecular response and complete cytogenetic response at 12 months compared to patients receiving imatinib. However, more patients in the bosutinib arm had dose interruptions, reductions or discontinuation of therapy due to adverse drug reactions.

Ponatinib is considered a third-generation TKI, as it contains a novel triple-bond linkage in its chemical structure that avoids the steric hindrance caused by the bulky isoleucine residue at position 315 in T315I BCR-ABL binding site cleft, providing clinical activity against this resistance phenotype. However, off-target inhibition of vascular endothelial growth factor receptor (VEGFR), PDGFR, SRC, c-Kit and other receptors may occur.[28] The EPIC trial was a phase III randomized trial comparing ponatinib to imatinib in patients with newly diagnosed CP-CML.[45] The study was terminated in October 2013 after events of arterial thrombosis were reported. The FDA subsequently released a Drug Safety Communication reporting an increased risk of life-threatening blood clots and narrowing of vessels within the extremities in patients who received ponatinib.[46] This agent also carries a Black Box Warning for vascular occlusion, heart failure, and hepatotoxicity.

Now, imatinib, dasatinib, nilotinib and bosutinib are all recommended for patients with CP-CML who are at low risk of progression according to the ELTS model.[6] In patients with intermediate or high risk of progression, recommended first-line treatment includes dasatinib, nilotinib, and bosutinib. Imatinib may also be used in this setting, although it is not preferred. There are no head-to-head comparisons of dasatinib, nilotinib, and bosutinib, and therefore the clinician should personalize the selection of first-line therapy in CP-CML.[4,6,26] Factors such as comorbidities, potential toxicities, drug–drug interactions, dosing schedule, cost, and patient and physician preference should all be considered. Due to the risk of serious toxicities, ponatinib is generally reserved for patients with a documented T315I mutation or for patients in whom no other TKI therapy is indicated.[4,6]

Monitoring for Response

⑤ Careful monitoring is necessary to guide clinician decision making for modification of therapy. Recommendations for monitoring include baseline molecular and cytogenetic assessment. Patients with CP-CML who have an optimal response have a complete hematologic response within 3 months, partial cytogenetic response within 6 months, complete cytogenetic response within 12 months and major molecular response within 18 months of starting treatment.[4,6] *BCR-ABL* transcripts should be evaluated by RT-PCR every 3 months and bone marrow cytogenetics performed at 3 months if RT-PCR is unavailable or 12 months if neither complete cytogenetic response nor major molecular response is achieved. Bone marrow cytogenetics are repeated at 18 months if the patient is not in major molecular response or did not have a complete cytogenetic response at 12 months. The loss of hematologic or cytogenetic responses or clonal evolution at any time should be considered a treatment failure warranting a change in therapy. *BCR-ABL* kinase domain mutation analysis is performed for patients who have an inadequate initial response at 3, 6, 12, or 18 months, have any sign of loss of response or demonstrate disease progression to AP or BC.

Although most patients attain a complete cytogenetic response on TKIs, very few patients achieve a complete molecular response. In a study of patients enrolled in the IRIS study, Hughes et al. reported that less than 5% of patients on imatinib have undetectable levels of *BCR-ABL* when analyzed by RT-PCR.[47] Recent data suggest that the level of residual disease is predictive of progression-free survival.[48] Cytogenetic and molecular responses secondary to imatinib are associated with event-free survival and risk of progression to AP or BC.[33] Patients who do not achieve a hematologic response by 3 months, cytogenetic response by 6 months or major cytogenetic response by 12 months fare significantly worse as compared to responders. In addition, a complete cytogenetic response and at least a 3-log reduction in *BCR-ABL* levels via RT-PCR correlated with a 100% survival without disease progression at 18 months. The risk of disease progression according to the Sokal scoring system predicted the rates of disease progression to be 3%, 8%, and 17% in low-risk, intermediate-risk, and high-risk patients, respectively.

Discontinuation of TKIs

The treatment of CML requires long-term therapy that can have significant adverse drug reactions and financial consequences. Discontinuation of TKI therapy with close monitoring has recently emerged as a possibility in carefully selected patients.[4,6] Candidates for discontinuation include those who achieve and maintain a major molecular response, or what is referred to as a deep molecular response (>4 log decrease in *BCR-ABL* RT-PCR or <0.01% *BCR-ABL* (IS) detection), for at least three years. Other criteria include no history of AP or BC, access to reliable response monitoring, and a thorough discussion of the risks and benefits of discontinuing therapy with the patient.

Studies of TKI discontinuation show that about 40% of patients who have achieved a deep molecular response remain in treatment-free remission (TFR) after stopping treatment.[49–51] Most patients who do relapse after stopping TKI do so within the first 6 months after cessation of treatment, and a molecular response is regained in almost all patients when the same TKI is promptly resumed.

An unexpected phenomenon of TKI discontinuation is "TKI withdrawal syndrome."[4,6,52] Pruritis and musculoskeletal pain requiring treatment are seen in up to 30% of patients. However, this phenomenon is reversible, and symptoms often rapidly disappear if TKI therapy is reinitiated.

Careful patient selection for discontinuation of TKI therapy, followed by close monitoring of *BCR-ABL* transcripts and restarting therapy if *BCR-ABL* levels rise may become standard management in the future.

TKI Resistance and Subsequent Treatment

Up to 25% of patients with CP-CML will develop intolerance or resistance to first-line BCR-ABL TKI therapy.[53] Dasatinib, nilotinib, and bosutinib have all demonstrated efficacy in imatinib-intolerant and resistant patients.[53,54] Patients who cannot tolerate or do not respond to imatinib in the first-line setting should be treated with dasatinib, nilotinib, or bosutinib.[4,6] Patients who do not respond to a second-generation TKI in the first-line setting should receive an alternate second-generation TKI. There are not enough data at this time to recommend one second-generation TKI over another in second-line therapy. Mutational analysis may be helpful in this setting, as well as consideration of concurrent disease states, prior therapy, and expected adverse drug reactions.

The most prominent mechanism of TKI resistance is the presence of point mutations in one or more areas of the ABL kinase. More than 100 different mutations have been discovered thus far. Many of these mutations can cause a conformational change in the ATP binding site, which greatly decreases the ability of the TKI to bind and inhibit kinase activity.[55] Imatinib binds to BCR-ABL by establishing a series of hydrogen bonds with side chains of amino acids within the kinase domain. Mutations that alter this surface can decrease the affinity of imatinib for BCR-ABL, potentially preventing binding entirely.[56] The T315I mutation, known as the "gatekeeper mutation," occurs directly within the imatinib binding site and completely disrupts imatinib binding.[57–59] This mutation occurs in up to 20% of patients and is important because it confers resistance not only to imatinib but also to all second-generation BCR-ABL kinase inhibitors.

The PACE trial evaluated the use of ponatinib in 449 patients with resistance or intolerance to prior TKI therapy or with the T315I mutation.[59,60] Complete cytogenetic response rate at 12 months and major molecular response rate were 66% and 56%, respectively, in patients with CP-CML and the T315I mutation. Ponatinib is now recommended in patients with the T315I mutation or in patients who have failed 2 or more TKIs.[4,6]

A phase II trial of omacetaxine was conducted in 62 CP-CML patients with a history of the T315I mutation.[61] Complete hematologic response was achieved in 77%, complete cytogenetic response in 16%, and major molecular response in 17% of evaluable patients.

Treatment of Accelerated Phase/Blast Crisis

The goal of therapy in AP or BC is to return the patient to CP.[62] All of the BCR-ABL TKIs can induce responses in AP- and BC-CML, but response rates are lower as compared with those in CP-CML.

Omacetaxine mepesuccinate (Synribo®) was approved by the FDA in October 2012 for the treatment of CP- or AP-CML with resistance or intolerance to two or more TKIs. Omacetaxine is a first-in-class cephalotaxine ester that inhibits protein synthesis independent of direct BCR-ABL binding.[63] It is a semisynthetic form of homoharringtonine derived from the *Cephalotaxus harrintonia* alkaloid. Efficacy with omacetaxine has been demonstrated in two patient groups: CP- or AP-CML resistant to two or more TKIs and patients previously treated with imatinib harboring the T315I mutation. In a combined analysis of two phase II studies for CP- and AP-CML, omacetaxine was administered at 1.25 mg/m^2 subcutaneously twice daily for 14 consecutive days every 28 days then for 7 days every 28 days as maintenance.[64] Of the 41 patients in AP, 14% achieved or maintained a major hematologic response for a median of 4.7 months. The median overall survival of these patients was 14.3 months.

Traditional therapy for BC-CML is cytotoxic chemotherapy in treatment regimens similar to acute leukemia induction.[4,6,62] Etoposide (VP-16), cytarabine (Ara-C), and carboplatin (VAC-regimen) has demonstrated efficacy in patients with BC-CML with a median overall survival of 7 months.[65] The BCR-ABL TKIs have demonstrated modest activity in BC-CML and they may be added to cytotoxic chemotherapy to improve outcomes. Clinical guidelines recommend induction chemotherapy for acute leukemia based on the type of BP-CML, lymphoid or myeloid, along with a BCR-ABL TKI.[4,6] A BCR-ABL TKI can also be used alone in those with myeloid BP-CML or with a steroid in those with lymphoid BP-CML. Evaluation for allogeneic HSCT should be performed in all patients in BP-CML.[4,6,62] Please refer to the HSCT section above for more information regarding the indications and timing of this approach.

Summary of Treatment Options

The current standard of care is for patients with newly diagnosed CP-CML to receive a BCR-ABL TKI.[4,6] Low-risk patients may receive imatinib, dasatinib, nilotinib, or bosutinib based on comorbid conditions, expected adverse drug reactions, and patient or physician preference. Patients with intermediate- or high-risk disease should receive dasatinib, nilotinib, or bosutinib in the front-line setting. The goal of disease monitoring in CML is to differentiate patients who have optimally responded to an initial course of TKI therapy from those at high risk for treatment failure. With imatinib, nilotinib, dasatinib, and bosutinib as appropriate options for initial therapy for newly diagnosed CP-CML, and ponatinib and omacetaxine approved for salvage therapy, clinicians have many treatment options before allogeneic HSCT is warranted. Future research opportunities will focus on how to select second-, third-, and fourth-line therapies and whether combination therapy provides additional long-term benefits.

CHRONIC LYMPHOCYTIC LEUKEMIA

Epidemiology and Etiology

CLL is a lymphoproliferative disorder characterized by the accumulation of functionally incompetent clonal B lymphocytes.[66,67] CLL is the most common form of leukemia in the United States but is rare in other countries, such as Japan and China.[68] It is estimated that 20,160 new cases of CLL will be diagnosed in the United States in 2022.[3] Occasional family clusters of CLL have been recognized, and first-degree relatives of patients with CLL are at three times the risk of developing a lymphoid malignancy as compared with the general population. Male sex, white race, family history, and advanced age are known risk factors for the disease. CLL is a disease of older adults, with a median age of 71 years, although 20% to 30% of CLL occurs in patients who are younger than 55 years of age.[66,67]

Pathophysiology

CLL cells are comprised of a neoplastic clone of $CD5^+$ cells, which express low levels of surface-membrane immunoglobulin M (IgM) and immunoglobulin D (IgD) compared to normal peripheral blood B cells.[66,67] Normal $CD5^+$ B lymphocytes are present in the lymph nodes and blood. Neoplastic $CD5^+$ cells accumulate in the lymph nodes and spleen because of the loss of apoptosis by either the overexpression of an oncogene, such as *BCL-1* or *2*, or loss of a tumor suppressor gene, such as *RB1*.[66] The BCL-2 protein is a major regulator of apoptosis or programmed cell death.

A monoclonal population of B cells with a similar surface antigen phenotype as CLL cells has been recently identified in patients up to several years before diagnosis of the disease.[67] This phenomenon, termed monoclonal B-cell lymphocytosis (MBL), appears to predict whether a patient is at risk for developing CLL over time.

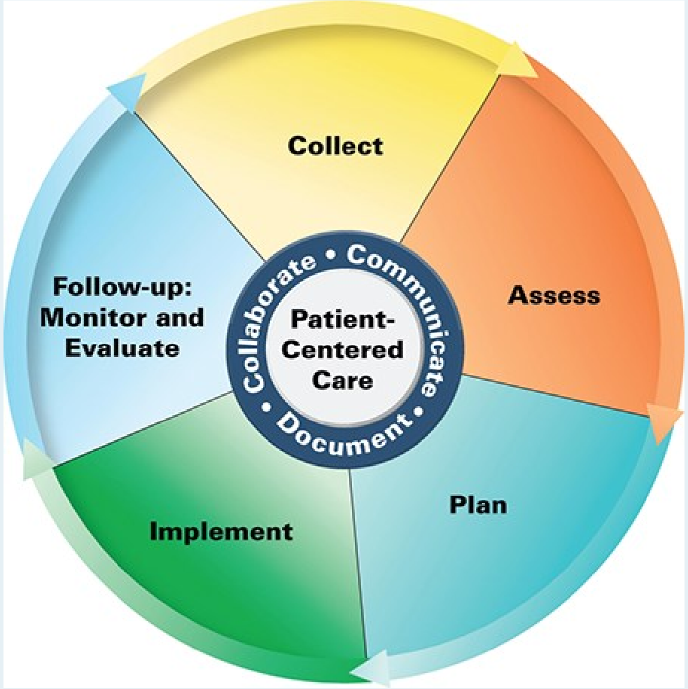
Although CLL lacks a common genetic target as observed in CML, B-cell-receptor signaling is a driver for CLL tumor survival.[66,67] Bruton's tyrosine kinase (BTK), a member of the Tec family of kinases, is essential for the activation of several constitutively active pathways for CLL cell survival. Phosphatidylinositol 3-Kinase (PI3K)-δ is a lipid kinase that plays a critical role in normal B-cell development, function, and transducing signals from receptors. The PI3Kδ signaling pathway is hyperactive in CLL and other B-cell cancers.

Cytogenetic abnormalities correlate with disease progression in CLL.[67] About 80% of patients with CLL have a karyotypic abnormality. The chromosomes that are most frequently involved include chromosomes 11, 12, 13, and 17.[67,69] Additional cytogenetic abnormalities may be acquired during therapy, particularly with deletions of chromosome 17, which have an adverse effect on survival.

About 4% to 10% of patients with CLL will undergo transformation of their disease to an aggressive lymphoma, most commonly non-Hodgkin lymphoma (diffuse large B-cell), which is termed as *Richter's syndrome*.[66,68,70] Richter's syndrome may be triggered by accumulation of additional cytogenetic abnormalities in the malignant clone of lymphocytes or by viral infections, such as Epstein-Barr virus.[70] Patients with Richter's syndrome will typically have a rapidly advancing disease course that mimics diffuse large B-cell non-Hodgkin lymphoma, but a small percentage of patients diagnosed with Richter's syndrome will transform into a Hodgkin lymphoma instead of a non-Hodgkin lymphoma.[68]

Patient Care Process

Patient Care Process for Chronic Lymphocytic Leukemia (CLL)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex)
- Medical history (personal and family), including personal history of infections
- Social history (eg, tobacco, alcohol, chemical exposure)
- Current medications (eg, complementary or alternative medicines, inducers or inhibitors of CYP3A4, QT prolonging medications, warfarin, over-the-counter medications including aspirin/NSAID use)
- Objective data:
  - Vital signs: height, weight, blood pressure, heart rate, respiratory rate, oxygen status
  - Laboratory data: CBC with differential, CMP
  - Flow cytometry (chromosomal and molecular markers of CLL) and bone marrow analysis if performed

  - Imaging studies (PET or CT scan, if performed)

Assess

- Performance status (ie, to determine if the patient is fit enough to receive chemotherapy)
- Comorbidities
- Cytogenetic and molecular markers of CLL (eg, high-risk disease with del(17p) or *TP53* mutation)
- Immunoglobulin heavy-chain variable (IGHV) mutation status
- Infection risk (eg, IgG <500 mg/dL (5 g/L) or absolute neutrophil count <500 cells/mm^3 [0.5×10^9/L])
- Symptoms of disease
- Patient and family's goals of care

Plan

- Observation (also known as "watch and wait") versus treatment
- Drug therapy based on high-risk CLL features, patient age, comorbidities, and schedule and route of therapy
- Monitoring parameters of efficacy (ie, disease response criteria) and safety (eg, myelosuppression, nausea, vomiting)
- Patient education (eg, goal of treatment, drug-specific education, medication adherence, food-drug and drug–drug interactions)

Implement

- Educate patient on all aspects of the treatment plan
- Patient compliance (intravenous vs oral)

Follow-up: Monitor and Evaluation of Response

- Evaluate efficacy using disease response criteria
- Assess safety and adverse drug reactions of treatment regimen
- Assess adherence to treatment plan (eg, patient-initiated delays vs toxicity-related delays)

**Collaborate with patient, caregivers, and other healthcare professionals.*

Clinical Presentation

CLINICAL PRESENTATION: Chronic Lymphocytic Leukemia

Constitutional Symptoms

- Fever, fatigue, weight loss

Physical Examination

- Lymphadenopathy (87%)
- Splenomegaly (54%)
- Hepatomegaly (14%)

Laboratory Tests

Peripheral blood

- Lymphocytosis
- Coombs-positive autoimmune hemolytic anemia
- Hyper- or hypogammaglobulinemia
- Monoclonal gammopathy
- Anemia
- Thrombocytopenia

Bone marrow

- Hypercellular
- Increased mature lymphocytes
- Increased megakaryocytes

Molecular markers

- Cytogenetics (11q, del(13p), del (17p))
- IGHV status
- CD38+ status
- ZAP-70 status

Staging and Prognosis

Survival times for patients with CLL are widely variable, with some patients succumbing to the disease within 3 years and others living into a second decade from the time of diagnosis.[66,71]

The Rai and the Binet staging systems are commonly used in CLL, with the Rai being favored in the United States and the Binet in Europe.[67,71] The Rai staging system has been combined into a risk classification scheme: low risk (stage 0), intermediate risk (stages I and II), and high risk (stages III and IV) with median survivals of greater than 10, 7, and 2 to 4 years, respectively.[72] While historically useful, the Rai and Binet staging systems are not predictive for individual patients because they do not include immunohistochemistry, cytogenetic, or molecular markers or abnormalities.

Immunoglobulin heavy-chain variable (IGHV) gene mutation status is an important predictor of survival outcomes.[66,73] Unmutated IGHV (≤ 2% mutated) is an independent indicator of poor prognosis and significantly decreased survival compared to mutated IGHV, regardless of the patient's disease stage.

Biomarkers, such as CD38 expression and ζ-associated protein 70 (ZAP-70) expression, have been explored as prognostic factors for CLL.[67,71] CD38 is a cell-surface antigen that is associated with early progression, shorter overall survival, and a poor response to fludarabine. ZAP-70 is an intracellular protein with tyrosine kinase activity. Once considered as simply a surrogate marker for unmutated IGHV, elevated ZAP-70 expression appears to predict for rapid CLL disease progression and independently correlates with prognosis.

Cytogenetic changes can be biomarkers of response to therapy. Specific chromosomal abnormalities and their associated survival are listed in Table 158-5. Deletion of the short arm of chromosome 17 (del[17p]), which corresponds to p53 silencing, is associated with the shortest survival times. Mutations in the p53 gene (ie, *TP53*) can also occur separately from del(17p) and are associated with uncontrolled cell proliferation and shorter overall survival.[67,71]

TABLE 158-5

Prognosis associated with cytogenetic changes in CLL

Chromosomal Abnormality	Median Overall Survival (months)
del(13)	133
del(12)	114
del(11q)	79
del(17p)	32

Treatment: Chronic Lymphocytic Leukemia

Desired Outcomes

The primary goals of treatment for CLL are to achieve and maintain a prolonged remission with minimal treatment-related toxicity.[67,71] The management of patients with CLL is highly personalized, with some patients receiving therapy on diagnosis, while other patients, particularly with early-stage disease, are managed expectantly. Indications for initiating treatment include disease-related symptoms (fatigue, night sweats, weight loss, and fever), threatened end-organ function, bulky disease, doubling of lymphocyte doubling time in less than 6 months, progressive anemia, and platelet count less than 100,000/mm^3 (100 × 10^9/L) or steroid-refractory autoimmune cytopenias.[68] Consideration of initial treatment options is based on several factors, including patient age and comorbid conditions, disease stage, and high-risk prognostic factors, such as del(17p) or *TP53* mutation.

Most patients diagnosed with stage 0 CLL do not require treatment and can be managed with observation.[67] In patients with stage I disease, treatment is controversial. A consistent survival benefit from early therapy has not been reported in asymptomatic patients.[71] In stages II through IV disease, treatment is required, with the goal of achieving a partial or complete remission.

Response definition varies based on the sites of involvement: resolution of lymphadenopathy and organomegaly, reduction of blood or marrow lymphocytes, and restoration of normal hematopoiesis.[67,71] An emerging goal of therapy is minimal residual disease (MRD), but this endpoint has only been recently introduced in CLL.[67] The clinical relevance of this assessment is currently undefined, as there is controversy as to whether this is a realistic treatment goal in patients with many comorbid conditions.

Cytotoxic Chemotherapy

Alkylating Agents

Historically, orally administered alkylating agents such as chlorambucil, given either alone or with corticosteroids, were used as the primary treatment for CLL.[74] Chlorambucil has been used in older, symptomatic patients as initial treatment for CLL, but its use is based on a small number of studies with no demonstrable survival advantage. Common dosing schedules for chlorambucil are intermittent pulse dosing of 15 to 40 mg/m^2 orally every 28 days or daily doses of 4 to 8 mg/m^2/day.[71] The dose of chlorambucil is often titrated to circumvent myelosuppression.

Bendamustine is an alkylating agent with a purine-derivative benzimidazole ring in its chemical structure that yields a compound that is non–cross-resistant with other alkylating agents. Bendamustine induces cell death via single- and double-stranded cross-links.[75] It is usually combined with an anti-CD20 monoclonal antibody, most often rituximab (eg, BR regimen). The use of bendamustine in the treatment of CLL is declining due to the availability of more targeted agents.[71]

Purine Analogs

Purine analogs, including fludarabine, 2-chlorodeoxyadenosine (cladribine) and 2-deoxycoformycin (pentostatin), are highly active in CLL, and fludarabine is the most widely studied.[67,73,74] Fludarabine is particularly useful in younger patients who can tolerate immunosuppressive chemotherapy. Although it was initially studied as a single agent in the treatment of CLL, fludarabine is now exclusively used in combination with other cytotoxic chemotherapy and/or immunotherapy. The most widely studied combination is fludarabine, cyclophosphamide and biologic therapy with rituximab (discussed below) in the FCR regimen.

Biologic Therapy

Monoclonal antibodies are a mainstay in the treatment of CLL. Rituximab is a chimeric monoclonal antibody that targets CD20 antigens expressed on B lymphocytes. Rituximab received FDA approval for the treatment of CD20-positive CLL in 2010. CLL cells have less prominent CD20 expression on their surface as compared to non-Hodgkin lymphoma, which may explain the lower clinical response in this setting. Rituximab as a single agent has moderate activity in CLL, with a 58% overall response rate reported with 9% complete responses.[67,71] Subsequent studies have used higher rituximab doses (up to 500 mg/m^2 per cycle) when given in combination with other agents. There are currently several biosimilar products of intravenous rituximab that are FDA-approved for use in the CLL population. Rituximab-arrx (approved in 2020), rituximab-pvvr (approved in 2019), and rituximab-abbs (approved in 2018) can all be substituted for rituximab. The decision regarding the specific product is usually based on the hospital or infusion center’s formulary and the patient’s insurance.

The FDA recently approved subcutaneous rituximab and hyaluronidase (1,600 mg/26,800 units) in combination with fludarabine and cyclophosphamide for the treatment of CLL. Subcutaneous administration of rituximab greatly reduces the time patients spend in an infusion center during their therapy by decreasing rituximab infusion from several hours to 15 minutes. Because of the large volume of rituximab, hyaluronidase is a component of the viscous, subcutaneous solution.[76] The hyaluronidase breaks down collagen, increasing the subcutaneous space for rituximab solution and facilitating absorption. Due to concerns over reactions, the intravenous formulation is given for the first treatment or cycle, and then the subcutaneous version is given with cycle 2 and beyond as long as the patient does not have an infusion-related reaction to intravenous rituximab.

Obinutuzumab is a glycoengineered type II anti-CD20 monoclonal antibody that does not induce translocation of CD20 monoclonal antibody complexes or complement-dependent cytotoxicity, but rather stimulates direct cell death via actin reorganization and homotypic adhesion.[77] Obinutuzumab, in combination with chlorambucil, was initially FDA approved in 2013 for patients with previously untreated CLL. Obinutuzumab is now combined with oral targeted therapies, such as acalabrutinib and venetoclax, in the frontline setting depending on the patient’s del(17p) status.[71]

Ofatumumab is a fully human monoclonal antibody to CD20 that was approved as single-agent therapy in 2009 for patients with CLL refractory to fludarabine and alemtuzumab. Ofatumumab is administered as an IV infusion with an initial dose of 300 mg, then four weekly doses followed by four monthly doses of 2,000 mg.

Targeted Therapy

The advent of oral targeted agents and anti-CD20 biologic therapy has made the use of traditional cytotoxic chemotherapy nearly obsolete in the treatment of CLL.[67] The availability of Bruton's tyrosine kinase inhibitors (BTKi), BCL-2 inhibitors and PI3K inhibitors has transformed CLL treatment over the past decade.

Bruton's tyrosine kinase (BTK) plays a key role in B cell survival, proliferation, adhesion, and cell migration. The introduction of BTKi has radically changed the treatment landscape of CLL. BTK is primarily expressed in B cells, but not plasma cells or T cells, making it an ideal target in CLL.[66] Ibrutinib is an orally administered compound that covalently binds to the cysteine-481 amino acid of the BTK enzyme and inhibits signaling of ERK, NF-κB, and cytosine phosphate-guanine–mediated tumor cell proliferation and migration.[67] Ibrutinib was FDA approved in 2014 for the treatment of CLL after at least 1 prior therapy and in 2016 for patients who are treatment-naive. Acalabrutinib is an irreversible second-generation BTKi with greater occupancy and improved selectivity compared to ibrutinib.[78] Zanbrutinib is a second-generation BTKi designed to minimize off-target kinase inhibition while achieving maximal exposure; it is more selective than ibrutinib for BTK and has less off-target activity against EGFR, TEC, and other kinases.[79]

Venetoclax is an orally administered selective BCL-2 inhibitor.[80,81] BCL-2 is an antiapoptotic protein that regulates the intrinsic apoptosis pathway. BCL-2 is overexpressed in CLL cells resulting in lymphocyte accumulation. BCL-2 inhibition with venetoclax results in apoptosis. Venetoclax was FDA approved in 2016 based on a phase I/IIb trial of venetoclax in 116 patients with relapsed CLL.

Idelalisib is a small-molecule inhibitor of PI3Kδ and interferes with the PI3Kδ-AKT signaling pathway leading to increased apoptosis.[67] Duvelisib is a dual small-molecule inhibitor of both PI3Kδ and PI3Kγ.[82] While PI3Kδ is involved in the survival and proliferation of B-cells, PI3Kγ is a mediator in the migration and differentiation of T-cells and macrophages. Inhibition of both the delta and gamma kinases blocks malignant B-cell survival and proliferation and disrupts the malignant microenvironment.

Tables 158-6 and 158-7 summarize dosing, drug interactions, adverse drug reactions, and monitoring of oral targeted agents used to treat CLL.

TABLE 158-6

Oral Targeted Agents in Chronic Lymphocytic Leukemia*

Drug	Brand Name	Dosing	Food–Drug Interactions	Drug–Drug Interactions
Acalabrutinib	Calquence®	• 100 mg orally twice daily • Avoid with severe hepatic impairment	• Avoid taking with proton pump inhibitors • Take 2 hours prior to taking an H_2-receptor antagonist • Separate from antacids by at least 2 hours • Avoid grapefruit, Seville oranges, star fruit, pomegranate	• Substrate of CYP 3A4 to an active metabolite (ACP-5862), 50% less potent than the parent compound • Strong CYP 3A4 inhibitors increase C_{max} by 3.9-fold and AUC by 5.1-fold • Strong CYP 3A4 inducers decrease C_{max} by 68% and AUC by 77% • Weak inhibitor of CYP 3A4/5, 2C8, and 2C9 • Weak inducer of CYP1A2, 2B6, and 3A4
Duvelisib	Copiktra®	25 mg orally twice daily	None	• Substrate of CYP 3A4, P-gp, and BCRP • Strong CYP 3A4 inhibitors increase C_{max} 1.7-fold and AUC 4-fold

				- Strong CYP 3A4 inducers decrease C_{max} by 66% and AUC by 82% - Moderate inhibitor of CYP 3A4
Ibrutinib	Imbruvica®	- 420 mg/day - 140 mg/day with mild hepatic impairment - 70 mg/day with moderate hepatic impairment	Avoid grapefruit, Seville oranges, and pomegranate	- Strong CYP 3A4 inhibitors increase C_{max} 6.7-fold to 29-fold and AUC 5.7-fold to 24-fold - Strong CYP 3A4 inducers decrease C_{max} >13-fold and AUC >10-fold - Minor substrate of CYP2D6
Idelalisib	Zydelig®	- 150 mg twice daily - Moderate or severe hepatic impairment, reduce dose to 150 mg daily	None	- Idelalisib is a CYP 3A4, 2C8, 2C19, UGT1A1, and P-gp inhibitor - Strong CYP 3A4 inducers decrease C_{max} by 58% and AUC by 75% - Strong CYP 3A4 inhibitors increase AUC 1.8-fold (no change in C_{max})
Venetoclax	Venclexa®	- Week 1: 20 mg once daily - Week 2: 50 mg once daily - Week 3: 100 mg once daily - Week 4: 200 mg once daily - Week 5: 400 mg once daily	- Take with a meal and a water - Avoid grapefruit, Seville oranges, star fruit, and pomegranate	- Substrate of CYP 3A4, P-gp, and BRCP - Inhibits CYP 2C8, 2C9, UGT1A1, P-gp, BCRP, and OATP1B1 - Concomitant strong 3A4 inhibitors, reduce dose to 100 mg - Concomitant moderate 3A4 inhibitors, reduce dose to 200 mg
Zanubrutinib	Brukinsa®	- 320 mg daily or 160 mg twice daily - 80 mg twice daily for severe hepatic impairment	Can be taken with or without food	- Primarily metabolized by CYP 3A4 - Concomitant strong or moderate CYP 3A4 inhibitors, reduce dose to 80 mg twice daily - Avoid concomitant use with strong CYP 3A4 inducers - Weak inhibitor of CYP 3A4 and CYP 2C19

AUC, area under the curve; C_{max}, maximum concentration; CYP, cytochrome P450; Pgp, P-glycoprotein; UGT, uridine 5’-diphospho-glucuronosyltransferase; BRCP, breast cancer resistance protein; OATP, organic-anion-transporting polypeptide.

Information obtained from each agent’s prescribing information.

TABLE 158-7

Monitoring of Oral Targeted Agents in Chronic Lymphocytic Leukemia*

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Acalabrutinib	Common ○ Dermatologic toxicity ○ Diarrhea	- CBC for myelosuppression - CMP for renal function and liver function	- Acalabrutinib increases the risk of bleeding; therapy may be held from 3-7 days prior to and after surgery

	○ Myalgias ○ Headaches ○ Fatigue ○ Infections ○ Myelosuppression Rare but Serious ○ Atrial fibrillation and flutter Hemorrhage	• ECG at baseline if cardiac risk factors	• Upon initiation, transient increase in lymphocyte count (not progression) • Headaches can usually be managed with acetaminophen and caffeine combination products
Duvelisib	Common ○ Edema ○ Skin rash ○ Fatigue ○ Dizziness ○ Electrolyte abnormalities (hypophosphatemia, hyponatremia, hyperkalemia, hypocalcemia) ○ Colitis ○ Diarrhea ○ Hepatotoxicity ○ Myelosuppression Rare but serious ○ Pneumonitis ○ PJP ○ Cytomegalovirus disease	• CBC for myelosuppression • CMP for liver function • Signs and symptoms of CMV reactivation or PJP • Signs and symptoms of diarrhea/colitis, intestinal perforation • Signs and symptoms of pneumonitis	PJP prophylaxis needed
Ibrutinib	Common: ○ Edema ○ Hypertension ○ Fatigue ○ Dizziness ○ Dermatologic toxicity ○ Myalgias and arthralgias ○ Fever ○ Myelosuppression ○ Renal toxicity Rare but Serious: ○ Hemorrhage ○ Cardiovascular effects: atrial fibrillation, atrial flutter, ventricular tachyarrhythmias ○ Nonmelanoma skin carcinoma	• CBC for myelosuppression • CMP for renal function and liver function • ECG at baseline if cardiac risk factors	• Ibrutinib increases bleeding risk; hold 3-7 days prior to and after procedures • If anticoagulation is necessary, avoid warfarin • Upon initiation, transient increase in lymphocyte count (not progression)
Idelalisib	Common ○ Myelosuppression ○ Hepatotoxicity ○ Diarrhea/Colitis	• CBC for myelosuppression • CMP for renal function and liver function • Signs and symptoms of	• Upon initiation, transient increase in lymphocyte count (not progression) • PJP prophylaxis needed

	○ Fatigue ○ Edema Rare but serious ○ Dermatologic toxicity ○ Gastrointestinal perforation ○ PJP ○ Pneumonitis	diarrhea/colitis, intestinal perforation • Signs and symptoms of pneumonitis • CMV reactivation	
Venetoclax	Common ○ Myelosuppression ○ Tumor lysis syndrome ○ Edema ○ Dermatologic toxicity ○ Fatigue ○ Dizziness ○ Electrolyte abnormalities (hypocalcemia, hyperkalemia, hypophosphatemia, hyponatremia) ○ Diarrhea ○ Nausea ○ Hepatotoxicity ○ Myalgias, arthralgias	• CBC for myelosuppression • CMP and uric acid for tumor lysis syndrome, renal toxicity, hepatoxicity	Risk for tumor lysis is based on patient's disease burden and rate of dose escalation
Zanubrutinib	Common ○ Myelosuppression ○ Upper respiratory tract infection ○ Rash ○ Bruising ○ Diarrhea Rare but Serious ○ Atrial fibrillation and flutter ○ Hemorrhage	• CBC for myelosuppression • CMP for renal function and liver function • ECG at baseline if cardiac risk factors	• Zanubrutinib may increase the risk of bleeding; therapy may be held from 3-7 days prior to and after surgery • Upon initiation, transient increase in lymphocyte count (not progression)

CBC, complete blood count; CMP, comprehensive metabolic panel; ECG, electrocardiogram; PJP, *Pneumocystis jiroveci* pneumonia.

**Information obtained from each agent's prescribing information.*

BTKis have several characteristic adverse drug reactions that require active management and may necessitate pharmacologic treatment.[83] Diarrhea occurs early and often in patients who receive ibrutinib and acalabrutinib, but is usually self-limiting and can be managed with supportive care.[66,71] A common toxicity unique to BTKi is redistribution lymphocytosis secondary to tumor cell mobilization to the peripheral blood.[66] Patient adherence to therapy should be stressed, as this lymphocytosis is *not* an indicator of disease progression and the BTKi should be continued at the standard dose. Resolution of lymphocytosis usually occurs after several weeks.

Minor bleeding or bruising may occur during BTK therapy, and up to 10% of patients may have serious bleeding events.[66] For patients having planned surgical procedures that are considered to be high risk for bleeding, BTKi may be held up to 7 days before and 7 days after the procedure; more minor procedures may warrant holding the BTKi for 3 days before and after the procedure.

BTKis are associated with cardiotoxic adverse effects.[84] Atrial fibrillation (AF) has been noted, most often with ibrutinib but also with acalabrutinib and zanubrutinib. In a phase III trial of acalabrutinib compared to ibrutinib for the treatment of relapsed CLL, the incidence of AF was significantly lower in the acalabrutinib arm.[85] The mechanism of this adverse drug reaction is poorly understood, but off-target inhibition of cardiac phosphoinositide 3-kinase (PI3K-AKT) has been proposed. The advanced age and comorbid conditions of many patients with CLL make this adverse drug reaction particularly troublesome.[86] If possible, modifiable risk factors for AF such as hypertension, heart failure, obesity and thyroid function should be identified and treated before the BTKi is started.[71,84] Patients with recurrent AF that is not medically controlled should avoid BTKis; AF that occurs during BTKi therapy should be managed according to current national guidelines.[84,86] The selection of drug therapy for AF during BTKi therapy may be problematic, as drug–drug interactions have been reported between BTKi and amiodarone or non-dihydropyridine calcium channel blockers. Further, the addition of anticoagulation may predispose the patient to bleeding, as noted above. If anticoagulation is necessary, non-warfarin alternatives should be considered since patients taking warfarin were excluded from many BTKi clinical trials.[71,84,86]

BTKis have also been associated with hypertension, with a potential continual rise in risk over time.[87] In retrospective studies, no single anti-hypertensive agent or class of drugs has been associated with the prevention or control of BTKi-related hypertension. The selection of drug therapy should be carefully considered to avoid drug–drug interactions with antihypertensive medications and the patient's current BTKi.[83]

Patients treated with venetoclax can develop tumor lysis syndrome when therapy is initiated.[83] The manufacturer recommends slow dose titration (known as "ramp up") from 20 mg daily to the target dose of 400 mg daily weekly over 5 weeks to minimize the risk of tumor lysis, although faster escalations of dosing may be used in select patient groups. Specific recommendations regarding inpatient versus outpatient initiation, dose escalation, and tumor lysis syndrome prophylaxis are based on disease burden and the patient's clinical status.[71] Drug–drug interactions must also be considered during venetoclax therapy.

Idelalisib, and duvelisib to a lesser extent, have been associated with immune-mediated adverse drug reactions such as colitis, intestinal perforation, elevated liver function tests and pneumonitis.[66,88] Patients should have complete blood counts and hepatic function monitored before initiation and throughout treatment. Patients receiving idelalisib or duvelisib should receive *Pneumocystis jiroveci* pneumonia prophylaxis and monitoring for CMV reactivation.[71]

Infections are a major cause of morbidity and mortality in patients with CLL, due to both the underlying disease and treatment-related immunosuppression.[66,71,83] Although hypogammaglobulinemia often occurs, intravenous immunoglobulin should only be considered in patients with serum IgG <500 mg/dL (5 g/L) and with recurrent sinopulmonary infections requiring hospitalization or intravenous antibiotics. Prevention of herpes virus infections with acyclovir or an equivalent should be considered, especially if patients are receiving purine analogs, bendamustine or corticosteroids. Hepatitis B reactivation may occur in patients treated with anti-CD20 monoclonal antibodies; screening should be conducted prior to initiation of therapy, and prophylaxis may be required. Finally, vaccination for influenza, pneumococcus and zoster should be administered as recommended by national guidelines; recombinant forms should be used and live vaccines should be avoided.

Hematopoietic Stem Cell Transplantation

The experience with the use of HSCT in CLL is limited. Although allogeneic HSCT may offer the potential of cure in CLL, the advanced age of most patients, reduced donor availability, and high treatment-related mortality precludes the routine application in the management of this disease.[71] Patients treated with allogeneic HSCT achieve higher remission rates and appear to have longer disease-free survival, but this approach is associated with high treatment-related mortality of about 40%.

Additionally, the new, targeted therapies provide additional options for disease control and overall survival advantages, so the role of allogeneic HSCT is further limited. Older patients who are not candidates for full-intensity allogeneic HSCT may be candidates for non-myeloablative allogeneic HSCT.

Figure 158-2 shows the molecular targets of the various chemotherapy, targeted, and biologic agents used to treat CLL.

Initial Therapy

An evaluation of the patient's fitness for therapy must be conducted before therapy is initiated. Up to 90% of patients with CLL have one or more comorbidities, which may influence the choice of therapy and the patient's treatment goals.[89] There is no standard tool to assess a patient's fitness for therapy at this time, although NCCN Guidelines currently base the choice of initial therapy on age (older or younger than 65 years), the presence of significant comorbidities, and the presence or absence of deletion 17p or *TP53* mutation.[71]

At present, conventional cytotoxic chemotherapy in CLL is only recommended in younger, fit patients with mutated IGHV. This recommendation is based on the CLL10 study, in which bendamustine and rituximab (BR) was compared to FCR in over 500 previously untreated, fit patients with CLL.[90] The FCR arm showed improved progression-free survival, but overall survival was not different between the treatment groups. A progression-free survival benefit was also seen in those who had mutated IGHV CLL with a median of 42.7 months versus a median of 33.6 months in those without an IGHV mutation. However, the benefit of improved progression-free survival with FCR was not observed in patients older than 65 years of age. Patients who received FCR experienced more grade 3 to 4 neutropenia and infections, as well as an increased risk of secondary myelodysplastic syndromes and leukemias. Therefore, FCR is now only recommended for the first-line treatment of younger, fit patients with IGHV-mutated CLL.[71]

Preferred regimens for initial therapy of younger, fit patients include ibrutinib, acalabrutinib with or without obinutuzumab, and venetoclax plus obinutuzumab.[71]

Ibrutinib plus rituximab was compared to FCR in 529 previously untreated patients with CLL who were less than 70 years of age without del(17p).[91] At 45 months, progression-free survival favored ibrutinib and rituximab. Improved progression-free survival was seen across subgroups, but was not observed in patients with mutated IGHV, which strengthens the recommendation for FCR in the first-line treatment of younger, fit patients with IGHV-mutated CLL as discussed above. Although this study examined the use of ibrutinib and rituximab, the true benefit of an anti-CD20 monoclonal antibody in this setting is not clear due to a lack of comparative studies, and therefore ibrutinib alone is recommended in the first-line treatment of CLL.[71,73]

The ELEVATE-TN study was a three-arm phase III trial that randomized 535 patients with untreated CLL to acalabrutinib plus obinutuzumab, acalabrutinib alone, or chlorambucil plus obinutuzumab.[78] Of note, acalabrutinib was continued until disease progression or unacceptable toxicity while chlorambucil was given for a specific period of time. At a follow-up of 24 months, both of the acalabrutinib-containing treatment arms had significantly longer progression-free survival (87% for acalabrutinib alone and 93% for the acalabrutinib plus obinutuzumab compared to 47% for chlorambucil plus obinutuzumab). Overall survival was not different between the three treatment groups.

In June 2019, the combination of venetoclax plus obinutuzumab was approved by the FDA for treatment naïve patients with CLL. In an open-label, phase III trial comparing venetoclax plus obinutuzumab with chlorambucil plus obinutuzumab, patients treated with venetoclax plus obinutuzumab had a significant improvement in progression-free survival over chlorambucil plus obinutuzumab after a median follow-up of 28.1 months. No benefit in overall survival has been reported in this trial.[80]

Patients who are 65 years of age or older or who have comorbid conditions may also be treated with ibrutinib, acalabrutinib with or without obinutuzumab, and venetoclax plus obinutuzumab in the first-line setting as discussed above.[71] The use of ibrutinib in the first-line treatment of older patients with CLL was explored in a phase III open-label trial in which 269 patients with CLL were randomized to ibrutinib or chlorambucil.[92] Patients who received ibrutinib had significantly longer progression-free and overall survival and higher overall response rates as compared to chlorambucil. Sustained increases in hemoglobin and platelet levels and greater improvements in quality of life were also observed with ibrutinib.

The combination of obinutuzumab plus chlorambucil is also a recommended regimen in the first-line treatment of patients who are 65 years of age or older or who have comorbid conditions.[71] The CLL11 study was a phase III trial that randomized 781 patients with untreated CLL and coexisting conditions to one of three treatment groups: single-agent chlorambucil, obinutuzumab plus chlorambucil, or rituximab plus chlorambucil.[93] Median progression-free survival was longer with obinutuzumab plus chlorambucil as compared to the other treatment arms. Overall survival also favored obinutuzumab plus chlorambucil as compared to rituximab plus chlorambucil. However, this regimen has fallen out of favor because of the data showing better progression-free survival outcomes with acalabrutinib and obinutuzumab.[71]

Preferred regimens for the first-line treatment of patients with del(17p) or TP53 mutation include ibrutinib, acalabrutinib with or without obinutuzumab, or venetoclax plus obinutuzumab, regardless of patient age or comorbidities.[71] Zanbrutinib is also currently recommended as an option for first-line treatment in this setting based on arm C of the SEQUOIA trial, which enrolled 104 patients with newly diagnosed CLL with del(17p).[94] All patients received zanubrutinib as a single agent. After a median of 18.2 months, the overall response rate was 94.5%, progression-free survival was 88.6%, and overall survival was 95.1%.

Treatment of Relapsed or Refractory CLL

Despite impressive results with the use of new agents in the first-line treatment of CLL, the disease remains incurable and nearly all patients will relapse. Selection of therapy for relapsed disease depends on age, performance status, previous therapy, and response and duration of previous therapy.[67,71] Recommended treatment regimens in this setting include BTKis, venetoclax plus rituximab, and PI3K inhibitors.

Patients who did not receive ibrutinib in the first-line setting may be considered for this agent at relapse. In a phase III trial, ibrutinib was compared to ofatumumab in patients with relapsed or refractory CLL with a primary endpoint of progression-free survival.[95] At 4 years of follow-up, the median progression-free survival was still not reached in patients who had received ibrutinib as compared to 8 months with ofatumumab, and 3-year overall survival continued to favor ibrutinib (59% vs 3%).[96] Patient-reported outcomes were significantly greater in patients who received ibrutinib. Acalabrutinib was compared to ibrutinib in patients with previously treated CLL with del(17p) or del (11q) in the phase III ELEVATE-RR trial.[85] Acalabrutinib was determined to be non-inferior to ibrutinib, with a median progression-free survival of 38.4 months in both arms as assessed by an independent review committee. Zanubrutinib is currently recommended as second-line or subsequent treatment of CLL in patients who are intolerant or have contraindications to other BTKis.[71] This recommendation is based on a single-arm phase II study of 91 patients with relapsed or refractory CLL. Overall response rate, as assessed by an independent review committee, was 84.6% at a median of 15.1 months.[97]

The combination of venetoclax plus rituximab was compared to bendamustine plus rituximab in 389 patients with relapsed or refractory CLL.[81] Progression-free and overall survival were both significantly higher in the venetoclax plus rituximab arm, and these benefits were maintained across all subgroups. A higher percentage of patients receiving venetoclax plus rituximab also had undetectable MRD at the end of therapy.

Idelalisib and duvelisib may also be considered in the relapsed and refractory setting.[71] In a randomized phase III trial, patients with relapsed CLL who had comorbidities that precluded them from being treated with standard chemotherapy were randomized to receive rituximab with either placebo or idelalisib.[98] The primary endpoint of progression-free survival was 20.3 months in the idelalisib group as compared to 5.5 months in the rituximab monotherapy group. Patients in the idelalisib group had a higher overall response rate and significantly longer overall survival. In an open-label, phase III clinical trial of previously treated patients, duvelisib showed improved progression-free survival over ofatumumab.[82] The improvement in progression-free survival was also observed in patients with high-risk cytogenetic markers.

For patients with relapsed or refractory disease who have del(17p) or *TP53* mutation, preferred treatment options include ibrutinib (if not previously received), acalabrutinib, and venetoclax with rituximab (all Category 1 recommendations in the NCCN Guidelines).[71] Other recommended regimens include duvelisib, idelalisib plus rituximab, and single-agent venetoclax.

Summary of Treatment Options

CLL is an incurable disease, and the goal of therapy is to achieve and maintain disease remission while minimizing the burden of treatment-related adverse drug reactions.[66,67] Therefore, patients should not be initiated on therapy unless symptomatic. The specific treatment depends on cytogenetics, age, and comorbidities. The NCCN guidelines recommend first-line treatment options based on the presence of deletion 17p or *TP53* mutation, age (older or younger than 65) and the presence of significant comorbidities.[71]

Historically, FCR has been the preferred initial therapy for symptomatic CLL in younger patients without significant comorbidities, but this regimen is now limited to younger, fit patients with IGHV mutation.[66,67,71] First-line choices for patients without del(17p) include ibrutinib, acalabrutinib with or without obinutuzumab, or venetoclax plus obinutuzumab. At relapse, therapy options include alternative regimens used in the first-line setting as well as idelalisib plus rituximab, duvelisib or zanubrutinib. Patients with del(17p) or *TP53* mutation may receive ibrutinib, acalabrutinib with or without obinutuzumab, zanubrutinib or venetoclax plus obinutuzumab as initial therapy, with alternative regimens employed at relapse.

Careful attention should be paid to the management of adverse drug reactions, and pharmacologic therapy to treat such effects must be carefully chosen to avoid drug–drug interactions (Tables 158-6 and 158-7). Cost must also be considered because many of the oral therapies are given for long periods of time. Patients with CLL are also at risk for opportunistic infections, and prophylactic therapy may be warranted. Future research in CLL will determine the optimum sequence, length, and goals of therapy in CLL, as well as management strategies for long-term adverse drug reactions of such therapies.

FCR	fludarabine, cyclophosphamide, rituximab
FDA	Food and Drug Administration
FISH	fluorescence in situ hybridization
GVHD	graft-versus-host disease
GVL	graft-versus-leukemia (effect)
HLA	human leukocyte antigen
HSCT	hematopoietic stem cell transplantation
Ig	immunoglobulin M
IGHV	immunoglobulin heavy chain gene
IFN-α	interferon alfa
IRIS	International Randomized study of Interferon vs STI571 trial
IS	international scale
MBL	monoclonal B-cell lymphocytosis
mRNA	messenger ribonucleic acid
NCCN	National Comprehensive Cancer Network
NSAID	nonsteroidal anti-inflammatory drug
PDGFR	platelet-derived growth factor receptor
Ph	Philadelphia chromosome
PI3K	phosphatidylinositol 3-kinase
RT-PCR	reverse-transcription polymerase chain reaction
STI	signal transduction inhibitor

TKI	tyrosine kinase inhibitor
VTE	venous thromboembolism
WBC	white blood cell
WHO	World Health Organization
ZAP-70	ζ-associated protein 70

SELF-ASSESSMENT QUESTIONS

1. MK is a 60-year-old male with newly diagnosed stage III CLL with deletion 17p and progressive symptoms of thrombocytopenia, anemia, and lymphadenopathy. Which of the following is the most appropriate treatment for MK at this point in his course?

   A. No therapy

B. Autologous stem cell transplant

C. Acalabrutinib and obinutuzumab

D. Imatinib

E. Rituximab

2. Patients receiving duvelisib for the treatment of CLL require which of the following supportive care measures?

A. Trimethoprim-sulfamethoxazole to prevent *Pneumocystis* pneumonia

B. Prophylactic cranial irradiation to prevent central nervous system involvement

C. Leucovorin rescue to prevent mucositis

D. Aspirin to prevent venous thromboembolism

E. Zoledronic acid to prevent bone lytic lesions

3. Which of the following predicts a more aggressive disease course and shorter remission with standard treatment options for CLL patients?

A. Age less than 65 years

B. Presence of the Philadelphia chromosome (translocation of chromosomes 9 and 22)

C. Presence of the cytogenetic abnormality involving deletion of chromosome 17

D. Having a confirmed sibling matched donor for allogeneic stem cell transplant

E. Presence of the cytogenetic abnormality involving deletion of chromosome 13

4. Which one of the following patients with CML would be the most appropriate candidate for an allogeneic stem cell transplant?

A. A 62-year-old male with newly diagnosed disease, sibling-matched donor available and no prior treatment for CML

B. A 45-year-old female with a sibling match and CML harboring a T315I mutation with disease that has progressed following salvage therapy with ponatinib

C. A 71-year-old female with refractory CML to imatinib and a second-generation tyrosine kinase inhibitor who has no suitable match for transplant

D. A 71-year-old male with refractory CML to front-line nilotinib who has a sibling match

E. A 31-year-old male in chronic phase with molecular response achieved with imatinib

5. JJ is a 69-year-old female with newly diagnosed stage III chronic lymphocytic leukemia (CLL) without del(17p) who is being considered for initial therapy. JJ's medical comorbidities include diabetes, congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), and diabetic neuropathy. Which one of the following treatment options would be the most appropriate first-line treatment for JJ?

A. Cytarabine and daunorubicin

B. Ibrutinib

C. Bendamustine and rituximab

D. Fludarabine, cyclophosphamide and rituximab

E. Idelalisib and rituximab

6. If a patient being treated for CML has the T315I mutation, which of the following is the most appropriate treatment option?

A. Hydroxyurea

B. Imatinib

C. Ponatinib

D. Interferon alfa

E. Dasatinib

7. The molecular marker in hematopoietic progenitor cells that defines CML is known as which of the following?

A. Philadelphia chromosome (translocation of chromosome 9 and 22)

B. Deletion of chromosome 17

C. Deletion of chromosome 13

D. Inversion of chromosome 16

E. Translocation of chromosome 15 and 17

8. Which one of the following most accurately describes the major toxicities in a patient receiving dasatinib?

A. Myelosuppression, myalgias, pleural effusion

B. SIADH, alopecia, mucositis

C. Seizure, peripheral neuropathy, constipation

D. Thromboembolism, somnolence, neuropathy

E. Nausea/vomiting, neuropathy, hearing loss

9. NH is a 67 year old male with a past medical history of hypothyroidism, hypercholesterolemia, atrial fibrillation, migraine headaches, and seasonal allergies. His medications include levothyroxine, rosuvastatin, warfarin, acetaminophen and cetirizine. He has recently been diagnosed with CLL and will be initiating therapy with acalabrutinib. Which of NH's medications should be changed based on the plan to initiate acalabrutinib?

A. Levothyroxine

B. Rosuvastatin

C. Warfarin

D. Acetaminophen

E. Cetirizine

10. Which of the following is the most appropriate first-line treatment for CML to induce and maintain disease remission with manageable toxicity?

A. Interferon alfa

B. Allogeneic stem cell transplant

C. Imatinib

D. Cytarabine

E. Hydroxyurea

11. MW is a 47 year old male with newly diagnosed chronic phase CML patient who was started on initial therapy with imatinib 400 mg orally daily. At 3 months, MW has not yet achieved a complete hematologic remission. What is the most appropriate course of action for MW at this time?

A. Repeat the bone marrow biopsy for cytogenetic analysis

B. Continue imatinib 400 mg orally daily until 6 months, then assess molecular response

C. Consider a second-generation tyrosine kinase inhibitor such as nilotinib

D. Hold imatinib and monitor molecular response for the next 3 months

E. Discontinue imatinib and start interferon alfa plus cytarabine

12. Which one of the following agents has a black box warning for QTc prolongation?

A. Ponatinib

B. Omacetaxine

C. Nilotinib

D. Imatinib

E. Lenalidomide

13. PS is a 47 year old male with CML who progressed to myeloid blast crisis despite having received three different tyrosine kinase inhibitors over the course of 22 months. What is the most appropriate course of action for further therapy for PS at this time?

A. Re-treat with the tyrosine kinase inhibitor therapy that was used first-line

B. There are no further treatment options for PS

C. Induction/remission therapy with cytarabine and an anthracycline

D. Hydroxyurea

E. Refer for consideration of hospice

14. KH is a 56-year-old female is receiving venetoclax and rituximab for second-line therapy for CLL. Which of the following toxicities associated with venetoclax should be monitored as KH initiates this new regimen?

A. Atrial fibrillation

B. Venous thromboembolism

C. Richter’s transformation

D. Tumor lysis syndrome

E. Hemorrhagic cystitis

15. Which of the following treatment settings is most appropriate for the use of idelelisib in CLL?

A. First-line treatment as a single agent in patients with del(17p)

B. In combination with rituximab as second-line treatment

C. Second-line treatment as a single agent in patients with del(17p)

D. In combination with fludarabine in patients with del(17p) as first-line treatment

E. In combination with conditioning chemotherapy for allogeneic stem cell transplant

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** The combination of acalabrutinib and obinituzumab is an NCCN category 1 preferred treatment regimen for patients with deletion 17p regardless of age.
2. **A.** Prophylaxis for *Pneumocystis jiroveci* pneumonia is recommended for patients who receive idelalisib or duvelisib for the treatment of CLL.
3. **C.** Newly diagnosed patients with del(17p) had a median time-to-progression following first-line of only 32 months.
4. **B.** Given that the patient has a T315I, ponatinib is the only TKI to target this DNA mutation. If the patient had disease progression on ponatinib, a hematopoietic cell transplant would be the only treatment option available.
5. **B.** Ibrutinib is a category 1 recommendation for patients >65 years old with significant comorbidities.
6. **C.** Ponatinib is the only TKI that targets the T315I mutation in CML.
7. **A.** The Philadelphia chromosome is present in 95% of patients with CML and drives the growth of the disease.
8. **A.** Myalgia and myelosuppression may be class-related adverse events of BCR-ABL inhibitors, but pleural effusions can occur in 20% of patients treated with dasatinib.
9. **C.** Patients who were taking warfarin were excluded from many BTKi tria due to concerns of increased bleeding risk. If prolonged anticoagulation is necessary, alternative agents such as enoxaparin or rivaroxaban should be considered.
10. **C.** Imatinib has 10-year survival data with over 80% of patients alive. Chemotherapy and interferon alfa have fallen out of favor in the standard of care. Newer agents such as nilotinib, dasatinib, and bosutinib may also be considered first-line agents.
11. **A.** Since the patient has not achieved the first milestone of hematologic remission, re-assessment of the bone marrow should be done to rule out other factors such as Philadelphia negative disease or a different CML clone. Depending on the results, second-line therapy can be selected and may include options such as dasatinib, nilotinib or bosutinib.
12. **C.** All TKIs can prolong the QTc, but nilotinib has the black box warning.
13. **C.** In the new TKI era, it is uncommon for patients to progress through multiple lines of TKI therapy to blast crisis. However, blast crisis is similar to acute leukemia and requires treatment with traditional chemotherapy agents.
14. **D.** Venetoclax causes rapid lysis of CLL cells resulting in tumor lysis. At initiation, venetoclax dose should be escalated weekly and patients at high risk for tumor lysis syndrome need to be admitted at initiation with dose escalation for monitoring and hydration.
15. **B.** Idelelisib is FDA approved in combination with rituximab for relapsed or refractory CLL regardless of 17p status.

DiPiro’s Pharmacotherapy: A Pathophysiologic Approach, 12e

Chapter 159: Multiple Myeloma

Amy M. Pick; Jared E. Matya

KEY CONCEPTS

KEY CONCEPTS

① Multiple myeloma (MM) is a cancer that develops in plasma cells, leading to excessive production of a monoclonal immunoglobulin.

② Most patients have skeletal involvement at the time of diagnosis, including bone pain and fractures. The acronym CRAB summarizes common clinical manifestations of MM and stands for hyper**c**alcemia, **r**enal failure, **a**nemia, and **b**one disease.

③ Primary therapy is initiated in patients with symptomatic MM, while patients with asymptomatic disease, such as smoldering myeloma or monoclonal gammopathy of undetermined significance, may be routinely observed.

④ Patients should be assessed for autologous hematopoietic stem cell transplantation (HSCT) eligibility before the initiation of treatment and, if eligible, hematopoietic stem cells should be harvested for transplantation following primary induction therapy. Autologous HSCT maximizes complete remissions and prolongs survival.

⑤ Initial therapy for patients with newly diagnosed MM should be personalized and based on their disease presentation, cytogenetic risk stratification, and functional status.

⑥ Initial therapy often consists of drug regimens incorporating a proteasome inhibitor, immunomodulatory drug, and dexamethasone. The regimen VRd (bortezomib, lenalidomide, and dexamethasone) is recommended for transplant eligible and ineligible patients with MM. A bortezomib-based regimen incorporating daratumumab is recommended by the Mayo mSMART guidelines in patients with high-risk cytogenetics.

⑦ Novel anti-myeloma drugs continue to be approved with encouraging results. Newer therapies include monoclonal antibodies, which are added to combination therapy, and chimeric antigen receptor T-cell therapy.

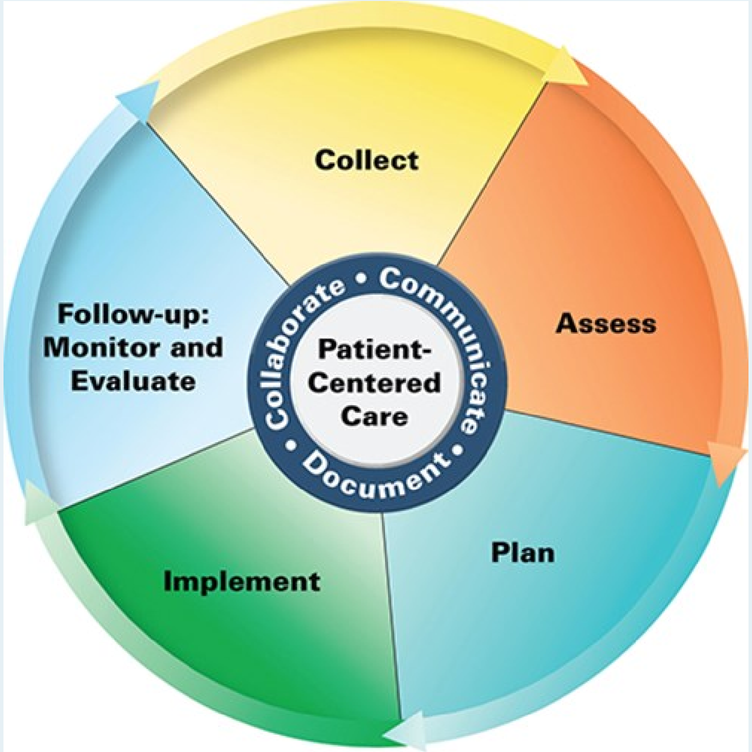
⑧ Maintenance therapies with lenalidomide or bortezomib may be used in both transplant-eligible and ineligible patients, with the goal of increasing progression-free survival.

⑨ There are numerous treatment options for patients with relapsed or refractory MM. Treatment selection depends on the patient’s performance status, drug toxicity profile, and prior drugs used for treatment.

⑩ The bisphosphonates, zoledronic acid and pamidronate, and denosumab are used to manage myeloma bone disease, resulting in decreased pain and skeletal-related events and improved quality of life.

PATIENT CARE PROCESS

Patient Care Process for Multiple Myeloma



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age at diagnosis)
- Patient medical history (personal and family)
- Patient comorbidities
- Patient organ function
- Current medications including over-the-counter (OTC) agents
- Prior treatment history for myeloma, if any
- Objective data
  - Labs including CBC, comprehensive metabolic panel, β_2-microglobulin
  - Results of bone scan

Assess

- Indication for therapy
- Candidate for autologous HSCT
- Impact of comorbidities on tolerance of therapy (eg, diabetes)
- Health literacy and adherence
- Emotional status (eg, presence of anxiety, depression)

- Ability/willingness to pay for antimyeloma treatment options (PO vs IV therapy)

Plan

- Drug therapy regimen (primary therapy vs relapsed therapy)
- Supportive care regimen (treatment of anemia, renal dysfunction, use of bone modifying agents)
- Monitoring parameters including efficacy and safety; frequency and timing of follow-up
- Patient education (eg, goal of therapy, schedule of treatments, adherence, self-monitoring)

Implement*

- Provide patient education
- Assess steps needed for insurance approval for oral/at home agents
- Ensure follow-up appointments are scheduled for active and supportive therapy

Follow-up: Monitor and Evaluate

- Response (minimum residual disease [MRD], M-protein)
- Safety (skeletal-related events, adverse drug reactions of antimyeloma therapy)
- Address supportive care concerns
- Adherence

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Watch the online YouTube video (https://www.youtube.com/watch?v=jdytgW5wKa4), “What is multiple myeloma” by Khan Academy Medicine. This 10-minute video provides an overview of multiple myeloma, highlighting classic myeloma disease presentation in the patient “Babs the CRAB,” and the pathogenesis and diagnosis of myeloma. This video increases the students’ understanding regarding the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION

① Multiple myeloma (MM) is a malignancy of plasma cells (ie, immunoglobulin-producing B lymphocytes).[1] The cancer is characterized by clonal proliferation and accumulation of a monoclonal immunoglobulin secreted from the plasma cell that can be measured in the plasma or urine. Patients with MM often have osteolytic bone lesions at the time of diagnosis, which is probably related to various bone-mobilizing cytokines secreted from the MM clone and bone marrow stromal cells. Other clinical manifestations include end-organ damage such as renal insufficiency, hypercalcemia, and anemia. The treatment of MM often consists of a three-drug combination incorporating a proteasome inhibitor (PI), immunomodulatory drug (IMiD), and dexamethasone. These regimens have improved response rates and outcomes compared to conventional chemotherapeutic agents. Although therapy is not curative, MM continues to be a remarkable example of bench-to-bedside translation in new drug development.

EPIDEMIOLOGY AND ETIOLOGY

The incidence of MM has increased globally, with a 126% increase in cases reported from 1990 to 2016.[2] In the United States, about 34,470 cases of MM were diagnosed in 2022, accounting for 12,640 deaths.[3] MM is a disease that affects older adults, with a median age at diagnosis of 69 years.[1,4] MM occurs more frequently in men than in women. The incidence of MM in Black individuals is twice that of White individuals, with Black patients having poorer survival rates.[5] Socioeconomic factors such as lack of access to care, medications, and clinical trials have been associated with poor outcomes.[5–7]

Risk factors for the development of MM are multifactorial. Inherited, societal, and environmental factors contribute to the incidence and outcomes of MM. Familial clusters of MM and multiple genetic mutations, including immunoglobin gene rearrangements, have been identified in the development and proliferation of MM.[8] Certain environmental influences have also been implicated with MM. Radiation exposure has been historically linked to the development of MM with atomic bomb survivors having a five times higher risk of MM. Even low levels of radiation may be a risk factor.[9] MM has been associated with exposure to various chemicals including pesticides, aromatic hydrocarbons, and petroleum products used in farming, cleaning works, mining, and other occupational groups working with these chemicals.[2]

PATHOPHYSIOLOGY

MM is a genetically heterogeneous disease characterized by abnormal clonal plasma cell infiltration in the bone marrow. Monoclonal gammopathy of undetermined significance (MGUS) and smoldering (ie, asymptomatic) MM may precede active MM. These conditions do not require treatment but do require active monitoring. MGUS is associated with the presence of monoclonal immunoglobulin in the blood (≤3 g/dL [30 g/L]), less than 10% clonal plasma cells in the bone marrow, and the absence of clinical manifestations of MM (eg, end-organ damage).[10,11] The conversion rate of MGUS to MM is about 1% per year. The molecular changes associated with the conversion of MGUS to MM are not clear, but genome-wide studies have identified several candidate genes associated with disease progression.[10,12] Smoldering MM is an advanced premalignant stage that is clinically distinct from MGUS with criteria including high monoclonal immunoglobulin in the blood (≥3 g/dL [30 g/L]) and 10% to 60% plasma cells in bone marrow with no clinical manifestations of MM. Although patients with smoldering MM have asymptomatic disease, the risk of progression to MM is about 10% per year for the first 5 years after diagnosis, about 3% per year for the next 5 years, and about 1% per year for the next 10 years.[13] Certain cytogenetic characteristics are associated with a higher risk of transformation to active MM including translocation of 4 and 14 (t(4;14)) and deletion of 17p (del (17p)).[10,14] Multiple genetic changes may occur over time leading to more symptomatic disease. Understanding the clinical features of the disease may help clinicians identify which patients are at high-risk for progression from MGUS or smoldering MM to active MM.

MM is characterized by the accumulation of malignant plasma cells in the bone marrow. Both MM and normal plasma cells are produced from differentiated B cells after antigen stimulation. Normal plasma cells will die within days to weeks after differentiation, whereas MM plasma cells are long-lived, with low proliferative activity.[1] MM was thought to originate from a single tumor cell, but it is now believed that MM is composed of genetically diverse clones and subclones that originate from one or more stem cells. The malignant plasma cell is involved in the unregulated production of a monoclonal antibody referred to as *M-protein.* MM cells are seldom seen in large quantities in the peripheral blood because of their close interaction with bone marrow stromal cells. MM cells are supported by a supportive bone marrow microenvironment that promotes the further expansion of MM clones. Molecules such as interleukin-6 (IL-6), vascular endothelial growth factor (VEGF), insulin-like growth factor-1 (IGF-1), and the transcriptional regulator nuclear factor kappa B (NF-κB) are part of the microenvironment and stimulate clonal growth, disease progression, and promote resistance to therapy (see Fig. 159-1).[15] Disruption of the microenvironment is an important strategy for therapy.

FIGURE 159-1

Pathogenesis of multiple myeloma. Multiple myeloma (MM) cells interact with bone marrow stromal cells (BMSCs) and extracellular matrix proteins via adhesion molecules, triggering adhesion-mediated signaling as well as cytokine production. This triggers cytokine-mediated signaling that provides growth, survival, and antiapoptotic effects as well as development of drug resistance. *(Reproduced, with permission, from Jameson JL, Fauci AS, Kasper DL, Hauser SL, Longo DL, Loscalzo J, eds. Figure 159-1 shows the molecules released during cytokine-mediated signaling and adhesion-mediated signaling. In a BMSC cell, NF-kappa B is added to the nucleus. The cell releases cytokines, IL-6, VEGF, IGF-1, and SDF-1 alpha, which result in cytokine-mediated signaling and adhesion-mediated signaling in the MM cells. During cytokine-mediated signaling, Raf forms MEK, which in turn forms p42/44 MAPK and promotes proliferation. JAK forms STAT3, which produces BCL-xL and Mcl-1 and promotes drug resistance and anti-apoptosis. During adhesion-mediated signaling, P13-K releases Akt and PKC. Akt releases Bad, NF-kappa B, and FKHR. Bad promotes drug resistance and anti-apoptosis. NF-kappa B promotes drug resistance and anti-apoptosis and produces cyclin D which results in cell cycle dysregulation. FKHR produces p21, which results in cell cycle dysregulation. PKC is involved in migration.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Multiple Myeloma

General Criteria

- Most patients present with symptomatic disease

Signs and Symptoms

- Bone pain (fractures, lytic lesions)
- Fatigue (anemia)
- Infection (reduced polyclonal response)
- Neurologic symptoms (nerve compression)
- Polyuria (hypercalcemia)
- Nausea and vomiting (hypercalcemia)

Laboratory Parameters

- Elevated M-protein
  - Plasma electrophoresis
  - Urine electrophoresis
  - Immunofixation

- Elevated serum creatinine
- Hypercalcemia
- Low hemoglobin
- Low albumin
- Elevated β_2-microglobulin
- Elevated C-reactive protein

Bone Marrow

- More than or equal to 10% plasma cells

Imaging

- Skeletal survey with MRI or low-dose CT scan, as indicated

Cytogenetics

- Chromosome 13 deletion
- Translocations of t(4;14), t(11;14), t(14;16), and t(14;20)
- Del (17p)
- Chromosome 1 amplification

② The clinical manifestations are related to the effects of MM cells on the bone microenvironment and the unregulated production of the M protein. Most patients with MM present with complaints of bone pain and fatigue at diagnosis. Initial laboratory evaluation often reveals hypercalcemia, renal insufficiency, anemia, and other abnormalities. Serum β_2-microglobulin is a useful measure of tumor burden. Skeletal evaluation shows gross abnormalities in most patients. Bone scans show abnormalities that often include lytic lesions, osteoporosis, and fractures. This group of findings—hyper**c**alcemia, **r**enal insufficiency, **a**nemia, and **b**one lesions—is often referred to by the acronym ***CRAB*** and is considered myeloma-defining events and suggests end-organ damage.[1,11] A confirmed diagnosis is defined by a bone marrow biopsy with 10% or more plasma cells, one or more myeloma-defining events, or biomarkers of malignancy.[11] The National Comprehensive Cancer Network (NCCN), International Myeloma Working Group (IMWG), and European Society of Medical Oncology (ESCO) have described criteria to diagnose MM.[11,16,17]

Following the diagnosis of MM, further workup analyzes and measures the quantity of the isotype of M-protein present. M-protein is a surrogate marker used to assess treatment response and disease progression. Serum protein and urine electrophoresis and serum and urine immunofixation identify the M-protein isotype secreted.[1] About 60% of patients have intact monoclonal immunoglobulin G (IgG), 20% have monoclonal IgA, and the remaining 20% secrete only monoclonal light chains. Antibodies are composed of two light chains, where antigen binds, and two heavy chains. Light-chain immunoglobulins, called Bence Jones proteins, can be secreted by the MM clone and excreted in the urine due to their low molecular weight, resulting in MM-associated renal failure. Serum-free light chains (SFCs) may also be measured, and these results may provide valuable information on the likelihood of disease progression.

Most patients have bone involvement at the time of diagnosis.[11] The effects of MM on the bone result from the abnormal production of cytokines, including IL-1, IL-6, tumor necrosis factor-α (TNF-α), and the receptor for activation of NF-κB ligand (RANK-L).[2] Bone involvement results from the activation of osteoclasts and inhibition of osteoblastogenesis and leads to bone destruction and resorption predisposing the patient to pathologic fractures and lytic lesions. Patients with MM are frequently anemic due to infiltration of the bone marrow with the MM clone and poor erythropoietin response. Patients can have clinically important hypercalcemia, which results from calcium mobilization due to bone resorption. Renal failure can occur as a result of high protein load from the monoclonal protein secretion and dehydration.

STAGING AND PROGNOSTIC FACTORS

Tumor cell features, tumor burden, and patient characteristics influence MM clinical outcomes. The revised International Staging System (R-ISS) is the primary staging system used to predict clinical outcomes for patients with MM. The R-ISS incorporates serum β_2-microglobulin, albumin, and lactate dehydrogenase levels, and high-risk chromosomal abnormalities to stage patients.[2,18] The R-ISS has largely replaced the older staging system, Durie-Salmon. Table 159-1 shows the R-ISS and median survival times for each stage.

TABLE 159-1

Revised-International Staging System (R-ISS) for Multiple Myeloma

Stage	Characteristics	Frequency (% of pts)	5-Year Survival (months)
I	Serum β_2-microglobulin <3.5 µg/mL (mg/L) and Serum albumin ≥3.5 g/dL (35 g/L)	28	82
	No high-risk cytogenetics		
	Normal LDH		
II	Not stage I or stage III	62	62
III	Serum β_2-microglobulin ≥5.5 µg/mL (mg/L) and	10	40
	High-risk cytogenetics [t(4;14), t(14;16), or del(17p)] or elevated LDH		

Reprinted, with permission, from Rajkumar SV. Updated Diagnostic Criteria and Staging System for Multiple Myeloma, American Society of Clinical Oncology Educational Book 36 (October 29, 2018) e418-e423.

Certain cytogenetic abnormalities are important prognostic factors. High-risk features associated with shortened overall survival include the presence of chromosomal 13 deletion (del 13), translocation of 4 and 14 (t(4;14)), and deletion of 17p (del (17p)).[11] The translocation of 11 and 14 (t(11;14) is the most common translocation, found in 20% of newly diagnosed patients. t(11;14) may be associated with intermediate outcomes and poor response to the novel agents used to treat MM.[19] The Mayo Clinic developed a risk-adapted approach, known as the mSMART (Mayo Stratification for Myeloma and Risk-Adapted Therapy), that categorizes patients into risk groups based on cytogenetics and gene expression profiling: high or standard risk.[20,21] Therapeutic options and treatment length are then recommended for each risk group. Additional prognostic factors generally represent the underlying pathologic changes associated with MM, including proinflammatory biomarkers (elevated C-reactive protein), tumor load (increased β_2-microglobulin), and dysregulated cellular growth (labeling index and marrow microvessel density).

TREATMENT

Desired Outcomes

The primary goal in the treatment of MM is to prolong the patient's survival and improve quality of life. This can be achieved by inducing a deep response (ie, MRD). Newly diagnosed MM patients who can tolerate chemotherapy will receive primary therapy where the goal is to achieve at least a major response. In transplant-eligible patients, primary therapy may be followed by transplant and maintenance therapy. The goals of these subsequent phases are to further improve response rates. With the integration of novel agents into therapy, progression-free survival and overall survival have steadily improved, and responses have increased in frequency, depth, and duration. Unfortunately, there is no convincing evidence that patients are cured of their disease.

General Approach

③ The decision to initiate treatment depends on whether the patient has symptoms of the disease. Early conventional treatment is not beneficial in patients with MGUS or smoldering MM.[10] Therefore, watchful waiting is the most common practice for patients with asymptomatic disease and is recommended by the NCCN guidelines.[11] However, this treatment paradigm is evolving with the availability of novel agents. Several small published studies, including a phase III randomized trial of 119 patients with high-risk smoldering MM, suggest that early treatment with novel agents may improve overall survival and delay time-to-progression.[10] Clinical trials are highly encouraged and close monitoring every 3 to 6 months should be considered in patients with high-risk smoldering MM.[11]

Pharmacotherapy plays a major role in the management of MM. In the last two decades, the availability of novel drugs such as IMiDs, PIs, and monoclonal antibodies has improved survival in patients with MM. Patients with MM are usually treated initially with combination drug therapy, and most patients will respond to that therapy (see "Initial Therapy" section). Eligible patients will also undergo autologous HSCT. Unfortunately, most patients will eventually relapse and require additional therapies.

The IMWG has developed uniform response criteria to assess response to drug therapy in patients with MM.[22] Clinical response to therapy is generally defined by a reduced serum and urine M-protein by immunofixation and electrophoresis and plasma cells in bone marrow. Numerous response types have been defined, including a stringent complete response (sCR), complete response (CR), very good partial response (VGPR), partial response (PR), and stable disease (SD). The depth-of-response correlates with improved outcomes and a complete response correlates with prolonged overall survival.[17,23] Since the depth of response is important, measurements of MRD with more sensitive assays such as quantitative polymerase chain reaction (Q-PCR) and next generation sequencing are included in the IMWG Response Criteria. Table 159-2 describes the most common types of clinical responses.[17]

TABLE 159-2

IMWG Response Criteria in Multiple Myeloma

Standard IMWG Response Criteria	
Stringent complete response	Complete response as defined below plus normal FLC ratio and absence of clonal cells in bone marrow biopsy by immunohistochemistry
Complete response	Negative immunofixation on the serum and urine and disappearance of any soft tissue plasmacytomas <5% plasma cells in bone marrow aspirates
Very good partial response	Serum and urine M-protein detectable by immunofixation but not on electrophoresis or ≥90% reduction in serum M-protein plus urine M-protein level <100 mg/24 hr
Partial response	≥50% reduction of serum M-protein plus reduction in 24 hours urinary M-protein by ≥90% or to <20 mg/24 hr If the serum and urine M-protein are unmeasurable, a ≥50% decrease in the difference between involved and uninvolved FLC levels is required in place of the M-protein criteria If serum and urine M-protein is unmeasurable, and serum-free light assay is also unmeasurable, ≥50% reduction in plasma cells is required in place of M-protein, provided baseline bone marrow plasma-cell percentage was ≥30%. In addition to these criteria, if present at baseline, a ≥50% reduction in the size of soft tissue plasmacytomas is required
Minimal response	≥25% but ≤49% reduction of serum M-protein and reduction in 24-hour urine M-protein by 50% to 89%. In addition to the above listed criteria, if present at baseline, a ≥50% reduction in the size of soft tissue plasmacytomas is also required
Stable disease	Not recommended for use as an indicator of response; stability of disease is best described by providing the time-to-progression estimates. Not meeting criteria for complete response, very good partial response, partial response, minimal response, or progressive disease
Progressive disease	Any one or more of the following criteria: Increase of 25% from lowest confirmed response value in one or more of the following criteria: Serum M-protein (absolute increase must be ≥0.5 g/dL [5 g/L]); Serum M-protein increase ≥1 g/dL (10 g/L), if the lowest M component was ≥5 g/dL (50 g/L); Urine M-protein (absolute increase must be ≥200 mg/24 hr); In patients without measurable serum and urine M-protein levels, the difference between involved and uninvolved FLC levels (absolute increase must be ≥10 mg/dL [100 mg/L]); In patients without measurable serum and urine M-protein levels and without measurable involved FLC levels, bone marrow plasma cell percentage irrespective of baseline status (absolute increase must be ≥10%); Appearance of a new lesion(s), ≥50% increase from nadir in the size of >1 lesion, or ≥50% increase in the longest diameter of a previous lesion >1 cm in short axis; ≥50% increase in circulating plasma cells (minimum of 200 cells/μL [0.2 × 10^9/L]) if this is the only measure of disease

Data from Reference 17.

Pharmacotherapy

⑥ Treatment of MM is based on the combination of dexamethasone with novel agents from two classes of drugs, the IMiDs and PIs. A three-drug regimen is preferred for primary treatment based on increased response rates and improved survival in clinical trials when compared to two-drug regimens. Although there is a lack of head-to-head comparative trials, several highly active combination regimens are available. VRd (bortezomib, lenalidomide, and dexamethasone) is a frequently used regimen based on improved outcomes and is considered standard of care.[14] Tables 159-3 and 159-4 show dosing and monitoring parameters for the commonly used agents in the treatment of MM. Dose reductions in elderly patients and patients experiencing adverse drug reactions are often required.

TABLE 159-3

Dosing of Drugs Used in the Treatment of Multiple Myeloma

Drug (Brand Name)	Dosing	Comments/Special Population
Lenalidomide (Revlimid®)	Induction therapy 25 mg/day PO on days 1-21 (28-day cycle) Maintenance therapy 10 mg/day, may be increased to 15 mg/day as tolerated	Adjust dose in renal impairment 30-60 mL/min (0.5-1.0 mL/s): 10 mg every 24 hours <30 mL/min (0.5 mL/s): 15 mg every 48 hours <30 mL/min (0.5 mL/s) (dialysis): 5 mg every 24 hours *_Note:_ Doses noted above are when used in combination therapy
Pomalidomide (Pomalyst®)	4 mg/day PO for 21 days (28-day cycle)	Mild-to-moderate hepatic impairment (Child-Pugh class A or B): 3 mg/day Severe hepatic impairment (Child-Pugh class C): 2 mg/day
Thalidomide (Thalidomide®)	200 mg/day	Start low in elderly adults; increase dose every 1-3 weeks
Bortezomib (Velcade®)	1.3 mg/m^2 SQ Days 1, 4, 8, and 11 Every 21 days	Reduce initial dose in hepatic impairment (serum bilirubin >1.5 × ULN) to 0.7 mg/m^2
Carfilzomib (Kyprolis®)	20 mg/m^2 on day 1 of cycle 1 and then 70 mg/m^2 on day 8; continue with 70 mg/m^2 for subsequent doses	Dosing for relapsed/refractory disease Alternate dosing schedules are available
Ixazomib (Ninlaro®)	4 mg/day PO Days 1, 8, and 15 Every 28 days	Renal impairment <30 mL/min (0.5 mL/s): 3 mg Hepatic impairment serum bilirubin >3 × ULN: 3 mg

Daratumumab (Darzalex®)	16 mg/kg (actual body weight) IV weekly × 8 weeks then 16 mg/kg IV every other week × 8 weeks, then 16 mg/kg every 4 weeks until disease progression	
Elotuzumab (Empliciti®)	10 mg/kg IV weekly on days 1, 8, 15, 22 for cycles 1 and 2; dosing changes with subsequent cycles	
Isatuximab-irfc (Sarclisa®)	10 mg/kg IV on days 1, 8, 15, 22 of a 28-day cycle for cycle 1; 10 mg/kg IV on days 1 and 15 of a 28-day cycle for subsequent cycles	
Panobinostat (Farydak®)	20 mg PO every other day for 3 doses/week (days 1, 3, 5, 8, 10, 12) of a 21-day cycle	Hepatic impairment serum bilirubin >1-1.5 × ULN: 15 mg serum bilirubin >1.5-3 × ULN: 10 mg serum bilirubin >3 × ULN: Not recommended
Selinexor	60-80 mg PO twice weekly (days 1 and 3) 100 mg PO once weekly	Dosing depends on regimen selected
Belantamab mafodotin	2.5 mg/kg IV every 3 weeks	
Melphalan flufenamide	40 mg IV once every 28 days	

TABLE 159-4

Adverse Reactions and Monitoring Parameters for Drugs Used in the Treatment of Multiple Myeloma

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Lenalidomide	Myelosuppression, rash, constipation, VTE, teratogenicity	CBC, LFTs, renal function, REMS Program (pregnancy testing), serum electrolytes and uric acid, thyroid function tests	Adjust dose in renal impairment VTE prophylaxis Secondary malignancies
Pomalidomide	Myelosuppression, rash, VTE, teratogenicity, infection	CBC, LFTs, renal function, REMS Program (pregnancy testing), serum electrolytes and uric acid	Adjust dose in hepatic impairment VTE prophylaxis
Thalidomide	Neuropathy, sedation, constipation, VTE, rash, neutropenia, teratogenicity	CBC, REMS Program (pregnancy testing), serum electrolytes and uric acid	Evening dose to decrease sedation Laxatives VTE prophylaxis
Bortezomib	Myelosuppression, neuropathy, infection including herpes zoster, gastrointestinal	CBC, LFTs, serum electrolytes and uric acid, neurologic examination	Antiviral prophylaxis

Carfilzomib	Myelosuppression, infection including herpes zoster, cardiac toxicity, infusion reactions, renal failure, neuropathy	CBC, LFTs, serum electrolytes and uric acid, renal function	Hydration to reduce risk of renal toxicity and TLS Dexamethasone premedication for infusion reactions Antiviral prophylaxis
Ixazomib	Myelosuppression, rash, neuropathy, infection including herpes zoster, gastrointestinal	CBC, LFTs, serum electrolytes and uric acid, renal function	Antiviral prophylaxis
Daratumumab	Severe infusion reactions, myelosuppression, infections, gastrointestinal	CBC	Premedicate with acetaminophen, diphenhydramine, methylprednisolone for infusion reactions Oral corticosteroid for 2 days following infusion Inhaled corticosteroids and bronchodilators may be needed for patients with COPD Antiviral prophylaxis is continued for 3 months after therapy
Elotuzumab	Severe infusion reactions, infections, hepatotoxicity, fatigue	LFTs	Premedicate with acetaminophen, H_1-receptor antagonist (ie, diphenhydramine), H_2-receptor antagonist (ie, ranitidine), dexamethasone for infusion reactions
Isatuximab	Severe infusion reactions, myelosuppression, infections, gastrointestinal, hypertension	CBC	Premedicate with acetaminophen, H_1-receptor antagonist (ie, diphenhydramine), H_2 receptor antagonist (ie, famotidine), dexamethasone for infusion reactions Consider antiviral and antibiotic prophylaxis
Panobinostat	Severe gastrointestinal toxicity (vomiting/diarrhea) resulting in dehydration, cardiac toxicity including QTc prolongation, myelosuppression, infection, hepatotoxicity	CBC, LFTs, serum electrolytes and uric acid, ECG	Anti-diarrheals Anti-emetics
Selinexor	Myelosuppression, infection, gastrointestinal, infection, neurotoxicity, ocular, electrolytes, hepatotoxicity, fatigue	CBC, serum electrolytes, LFTs, serum creatinine, neurologic, vision	Moderate-high emetic risk-administer with 5-HT_3 antagonist Specific dose adjustments for toxicity
Belantamab mafodotin	Infusion reactions, myelosuppression, electrolytes, hepatotoxicity, ocular, including vision loss	CBC, REMS-ophthalmic exam (baseline, before each dose), serum electrolytes	No premedications unless the patient experiences infusion reaction Lubricating eye drops QID while on therapy Avoid contact lenses

Melphalan flufenamide	Myelosuppression, infection, gastrointestinal, secondary malignancies	CBC	Moderate emetic risk-administer with 5-HT_3 antagonist Specific dose interruptions/reductions for toxicity

CBC, complete blood count; REMS, Risk Evaluation and Mitigation Strategy; VTE, venous thromboembolism.

Conventional Chemotherapy

Novel regimens have replaced conventional chemotherapy in the treatment of MM. Conventional drugs such as melphalan and cyclophosphamide may be combined with novel agents to improve overall survival, but their use is limited.[7] High-dose melphalan is commonly used in the conditioning regimen for patients with MM before autologous HSCT.

Corticosteroids

Corticosteroids are the cornerstone of MM therapy. Dexamethasone is incorporated into most treatment regimens, given in higher doses than those used in the treatment of other diseases. High-dose dexamethasone is associated with a higher risk of infection and central nervous system toxicity so it should be used with caution, particularly in older patients.[24] In current regimens, PIs and IMiDs are combined with dexamethasone to maximize initial response rates.

Immunomodulatory Drugs

IMiDs are incorporated into most treatment regimens for MM. Three IMiDs, thalidomide, lenalidomide, and pomalidomide, are approved for the treatment of MM, with lenalidomide most frequently utilized. Although thalidomide was the initial IMiD studied in MM, it has been largely replaced by lenalidomide due to increased potency and fewer adverse drug reactions. Thus, the discussion below on IMiDs will primarily focus on lenalidomide. IMiDs are often used in combination with a PI and dexamethasone to treat newly diagnosed and previously treated MM.

IMiDs have complex immune effects and block several pathways that are involved in disease progression in MM.[25] While not fully understood, IMiDs have anti-angiogenic and anti-inflammatory properties that directly or indirectly affect MM cells. IMiDs decrease the production of cytokines and growth factors that are believed to have a role in the pathogenesis of the disease, such as IL-6, TNF-α, and VEGF. IMiDs may also inhibit NF-κB activation, either directly or indirectly via TNF, which results in increased apoptosis of the MM clone. Further discussion of NF-κB can be found in the PIs treatment section. IMiDs also induce IL-2 mediated T-cell proliferation including natural killer cell activity. Figure 159-1 shows the proposed involvement of cytokines on MM cells.

A major concern with IMiDs is the rates of VTE. Patients with MM have up to a ninefold increased risk of VTE for the first 6 to 12 months of therapy compared to patients without MM.[26] The risk of VTE is also increased when IMiDs are combined with dexamethasone- or anthracycline-based chemotherapy. The underlying mechanism for thrombosis in these patients is unknown but is likely multifactorial. The IMPEDE VTE score is a VTE risk stratification tool that has been developed and validated to assist clinicians with the identification of high-risk VTE patients and with the appropriate selection of VTE prophylaxis.[27] That tool incorporates IMiD use in addition to other factors. NCCN guidelines have adopted the IMPEDE VTE score in their VTE prevention guidelines because the tool better predicts VTE in MM as compared to previously published guidelines.[27] Prophylactic aspirin may be an option for patients at low risk of VTE. High-risk patients should receive LMWH, warfarin (target INR 2-3) or a direct oral anticoagulant indefinitely while on MM therapy.[11] The use of direct oral anticoagulants is a recent addition to the NCCN guidelines and is based on emerging literature showing them to be safe and effective.[11] Apixaban has the most evidence to support its use in patients with MM.[28,29]

IMiDs are considered teratogenic based on the known teratogenicity of thalidomide. All of the IMiDs have black box warnings for the potential for severe birth defects and embryo-fetal death. The drugs are commercially available through restricted distribution programs and require enrollment into their respective Risk Evaluation and Mitigation Strategy (REMS) programs. The intent is to encourage safe use of the medication and minimize the risk of fetal exposure.

Table 159-4 shows additional adverse drug reactions for IMiDs.

Lenalidomide

Lenalidomide is a potent thalidomide analog and shares a similar mechanism of action to other IMiDs by targeting the microenvironment. Lenalidomide can be used as primary therapy in transplant-eligible or -ineligible patients, in relapsed/refractory MM and as maintenance therapy following transplant. Lenalidomide is preferred over thalidomide because of its improved toxicity profile.

Lenalidomide is Food and Drug Administration (FDA)-approved for the treatment of newly diagnosed patients with MM. In this setting, the doublet of lenalidomide and dexamethasone was compared with dexamethasone alone. The trial was halted when a planned interim analysis showed the combination to be more active than dexamethasone alone, with increased progression-free survival and overall response rate in the combination arm.[30] Subsequent trials examined the addition of a third agent, bortezomib, to the lenalidomide-dexamethasone regimen. A phase III study reported longer median progression-free and overall survival with the triplet regimen compared to the doublet lenalidomide and dexamethasone.[31] The regimen of bortezomib, lenalidomide, and dexamethasone is a category 1 NCCN recommendation for the primary treatment of MM patients regardless of transplant eligibility.[11] Other PIs and monoclonal antibodies may also be combined with lenalidomide and dexamethasone for primary therapy.

Lenalidomide is also used in the treatment of relapsed or refractory MM. Initial trials randomized patients to receive either lenalidomide (25 mg/day on days 1-21 of a 28-day cycle) and high-dose dexamethasone or high-dose dexamethasone alone. In one trial, patients receiving lenalidomide and dexamethasone had overall response and CR rates of 61% and 14%, respectively, compared with 20% and 0.6% in the dexamethasone alone group.[32] The improved response rates translated into a longer median overall survival in the lenalidomide and dexamethasone groups. Similar results were reported in the second trial.[33] Other trials have evaluated the combination of lenalidomide and dexamethasone with a third agent for relapsed/refractory MM. The triplet regimens of lenalidomide, dexamethasone, and carfilzomib, ixazomib, elotuzumab, or daratumumab show longer progression-free survival, resulting in the approval of these regimens for the treatment of relapsed/refractory disease.[30]

The most appropriate dosing of dexamethasone with lenalidomide has also been evaluated. An open-label noninferiority phase III trial addressed this question in untreated patients with MM.[34] Patients were randomized to lenalidomide and high-dose dexamethasone (40 mg on days 1-4, 9-12, and 17-20 of each 28-day cycle) compared with lenalidomide and low-dose dexamethasone (40 mg/week). Patients who received lenalidomide with low-dose dexamethasone had longer 2-year overall survival and less toxicity than those who received lenalidomide with high-dose dexamethasone. The trial was halted after a second interim analysis and patients were allowed to cross-over to the low-dose arm. Patients in the lenalidomide plus high-dose dexamethasone arm had a 26% incidence of VTE compared to a 12% rate in those randomized to the lenalidomide plus low-dose dexamethasone arm.[34] The improved survival in the low-dose dexamethasone arm is likely related to lower mortality from adverse drug reactions, particularly VTE. Deaths in the high-dose dexamethasone group usually occurred during the first 4 months in older patients.

Lenalidomide is better tolerated than thalidomide. Lenalidomide causes less neurotoxicity, somnolence, and constipation but more myelosuppression than thalidomide. Patients receiving lenalidomide have an increased risk of secondary malignancies, particularly patients >74 years old receiving maintenance lenalidomide.[35] Multiple cycles of lenalidomide can impair stem cell mobilization. The IMWG recommends that transplant-eligible patients receiving lenalidomide have stem cells collected within the first four cycles of therapy.[11,36] Mobilization with chemotherapy or plerixafor may be utilized if stem cell collection is decreased.

Pomalidomide

Pomalidomide is a third-generation IMiD used in the treatment of MM. It is FDA-approved in relapsed MM in patients who have received at least two prior therapies, including lenalidomide and a PI. Pomalidomide is not approved for first-line therapy. Its initial approval was in combination with low-dose dexamethasone, where the pomalidomide combination demonstrated a progression-free and overall survival benefit versus high-dose dexamethasone.[37] Following that approval, pomalidomide was evaluated as part of various three-drug combinations. Pomalidomide shows good efficacy in patients who are refractory to lenalidomide and/or PI therapy. In refractory patients or those experiencing early relapse (<60 days after last therapy), the NCCN recommends pomalidomide, dexamethasone, and any of the available PIs as a preferred regimen after at least two lines of prior therapy. Similarly, regimens including pomalidomide and dexamethasone in combination with an anti-CD38 monoclonal antibody or elotuzumab are recommended for patients previously treated with lenalidomide and a PI.[11] Overall, pomalidomide is well tolerated with a toxicity profile similar to that observed with lenalidomide, except for a slightly higher incidence of peripheral neuropathy.

Proteasome Inhibitors

⑥ PIs are incorporated into most treatment regimens for MM. Three PIs, bortezomib, carfilzomib, and ixazomib, are approved for the treatment of MM. Bortezomib is the backbone of many regimens while the newer generation drugs seek to improve the toxicity profile, specifically lessening the degree of neuropathy. PIs are often used in combination with an IMiD and dexamethasone for the treatment of primary and relapsed/refractory MM.

PIs inhibit the proteasome and NF-κB activation. The proteasome is a protease complex responsible for degrading cytosolic proteins that are conjugated to ubiquitin. Ubiquitin is a 76-amino acid protein that tags various proteins for destruction.[38] By reversibly binding to the chymotrypsin site in the catalytic core of the 26S proteasome, bortezomib inhibits the degradation of these targeted proteins. Ixazomib is a reversible inhibitor while carfilzomib irreversibly binds to the chymotrypsin site, which explains the differences in pharmacokinetics among the drugs in this class.[38]

As discussed earlier, NF-κB activity is increased in MM. In the cytosol, NF-κB is bound to and is inhibited by IκB. The proteasome degrades IκB. When the proteasome is inhibited, cytosolic concentrations of IκB remain high, and NF-κB is retained in the cytosol as an inactive complex. The resulting inhibition of the NF-κB signal leads to a reduction in cytokine production and growth inhibition of the MM clone. Other proteins involved in cell-cycle regulation and apoptotic signaling that may be affected by PIs include p53 and map kinase.[38]

Bortezomib

Bortezomib was the first drug in the class of PIs and continues to be the backbone of many regimens used in the treatment of MM. A 2016 Cochrane review concluded that bortezomib treatment improves response rates, progression-free survival, and overall survival and should be considered standard of care for the treatment of MM.[39] Bortezomib has been extensively studied and is approved as primary therapy for newly diagnosed and relapsed/refractory MM. Bortezomib was initially approved in 2003 under the FDA's accelerated approval process for relapsed or refractory MM in patients who had failed at least two prior therapies. The approval was based on a phase II trial in which refractory MM received 1.3 mg/m^2 of bortezomib twice weekly for 2 weeks followed by 1 week of rest. Patients received up to eight cycles. The overall response rate was 35% (includes minor responses) with seven (3.6%) patients achieving a CR.[40] Subsequently, a large phase III study (Assessment of Proteasome Inhibition for Extending Remissions [APEX] trial) demonstrated that bortezomib had superior activity compared with high-dose dexamethasone in relapsed MM. Bortezomib-treated patients had higher CR and PR rates, longer median time-to-progression, and improved 1-year overall survival compared with patients receiving dexamethasone.[41] The differences in each of these end points were statistically significant. The results from this study led to expanded FDA approval in 2005 to include patients who had relapsed after one therapy. Numerous trials have examined bortezomib in combination with monoclonal antibodies, IMiDs, and/or traditional chemotherapy for relapsed and refractory MM. Various triplet combinations include bortezomib and dexamethasone with lenalidomide or daratumumab.[11]

Bortezomib is extensively used in the primary treatment of MM. As discussed earlier, the triple drug regimen of lenalidomide, bortezomib, and dexamethasone is the preferred treatment regimen for primary therapy in patients regardless of transplant eligibility. The inclusion of bortezomib in three- or four-drug combinations improves response rates and increases progression-free and overall survival. Bortezomib-based therapies may also be preferred in patients with high-risk disease, based on data that shows bortezomib may be able to overcome certain cytogenetic abnormalities, including the t(4;14) translocation.[42]

Bortezomib can cause serious adverse drug reactions. The most common adverse drug reactions are mild-to-moderate fatigue and gastrointestinal toxicities. Neuropathy occurs frequently and is the most common cause of discontinuation of therapy. Other important toxicities are listed in Table 159-4. An increased risk of shingles has been reported in bortezomib-treated patients, and the NCCN guidelines recommend herpes zoster prophylaxis.[11] Bortezomib-based therapy is an attractive option for those patients with renal dysfunction since renal dose modifications are not required. In patients with renal dysfunction, the NCCN recommends the combination of bortezomib-cyclophosphamide-dexamethasone, as lenalidomide requires renal dose adjustments. If the patient's renal function improves after initial treatment with bortezomib-cyclophosphamide-dexamethasone, it is reasonable to switch to bortezomib-lenalidomide-dexamethasone.[11] Unlike lenalidomide, bortezomib does not affect stem cell mobilization.

Since neurotoxicity is a concern with bortezomib, investigators have explored modifying the route of administration and dosing schedule of bortezomib. In a phase III trial in relapsed MM, therapeutic equivalence was found between intravenous and subcutaneous routes of administration.[11] In addition, subcutaneous administration offers the potential advantage of administration in patients without IV access, is more convenient, and has a lower risk of peripheral neuropathy. Subcutaneous bortezomib administration is now the preferred route of administration.[11] Dose schedules have also been modified to decrease toxicity-related treatment delays. Once-weekly bortezomib has been compared with twice-weekly dosing with similar overall response rates.[11] The once-weekly schedule was associated with fewer dose reductions, and the risk of neuropathy was similar.

Carfilzomib

Carfilzomib is a second-generation, irreversible PI approved for patients with relapsed and refractory disease. Its mechanism, higher selectivity for the chymotryptic site of the 20S proteasome, and toxicity profile are distinct compared to bortezomib.[38] The dosing schedule is also different than bortezomib. Carfilzomib is more potent, yet tolerable with two consecutive daily doses or once weekly dosing. Collectively, clinical trials start with carfilzomib 20 mg/m^2 IV over 10 to 30 minutes on the first cycle/week and increase to 27 to 70 mg/m^2 depending on tolerability and dosing frequency.[43,44]

Numerous trials have examined carfilzomib in the treatment of progressive or relapsed MM. The ASPIRE trial showed the addition of carfilzomib to a lenalidomide-dexamethasone backbone improved progression-free survival, overall survival, and health-related quality of life without any change in adverse drug reactions.[44] The incidence of neuropathy was similar in both arms. Carfilzomib-dexamethasone was compared to bortezomib-dexamethasone in relapsed or refractory MM in the head-to-head Phase III trial (ENDEAVOR). Median progression-free survival was longer with carfilzomib as compared to the bortezomib group.[45] A second interim analysis showed that carfilzomib also improved median overall survival as compared to bortezomib.[46] Based on these data, carfilzomib in combination with lenalidomide-dexamethasone or dexamethasone is an NCCN category 1 recommendation for previously treated MM.[11] Additional studies are evaluating carfilzomib with traditional chemotherapy and other novel drugs.

The activity of carfilzomib in combination regimens as first-line treatment is also impressive. The phase III, open-label, ENDURANCE trial compared bortezomib, lenalidomide and dexamethasone and carfilzomib, lenalidomide and dexamethasone in the first-line setting for standard and intermediate-risk patients with MM.[47] The trial showed similar progression-free survival between the two arms. Carfilzomib was associated with less neuropathy but increased pulmonary and cardiac adverse events.[47] According to the NCCN guidelines, certain carfilzomib-containing regimens may be used for primary therapy, especially in patients with peripheral neuropathy.[11]

The toxicity profile of carfilzomib differs from that of bortezomib. The incidence of peripheral neuropathy is less with the second-generation PIs which should be considered when treatment is selected. The ENDEAVOR trial reported a lower risk of grade 2 or higher peripheral neuropathy in patients who received carfilzomib as compared with bortezomib.[45,46] Carfilzomib is associated with serious cardiac and pulmonary toxicities. The cardiovascular adverse events include congestive heart failure, hypertension, arrhythmias, and ischemia. A meta-analysis of 24 studies reported the rate of cardiovascular events as 18.1%, with higher doses of carfilzomib (≥45 mg/m^2) associated with higher rates of cardiovascular events.[47] The pulmonary adverse events of dyspnea, cough, respiratory tract infections, and pneumonia are also of concern.[48] Clinicians should monitor patients for carfilzomib-related cardiac and pulmonary symptoms and initiate symptom management when necessary.

Ixazomib

Ixazomib is the first oral PI approved for the treatment of MM. It is given once-weekly as second-line therapy in combination with lenalidomide and dexamethasone. The approval is based on the TOURMALINE-MM1 phase III trial, which showed the addition of ixazomib to lenalidomide and dexamethasone prolonged progression-free survival in patients with relapsed or refractory MM as compared with lenalidomide and dexamethasone alone.[49] The TOURMALINE-MM2 phase III trial evaluated ixazomib, lenalidomide, and dexamethasone in newly diagnosed patients with MM. The trial showed improved response rates with the addition of ixazomib to lenalidomide and dexamethasone but failed to reach statistical significance in progression-free survival.[50] The results of this study led to an NCCN category 2B recommendation for ixazomib, lenalidomide, dexamethasone in the first-line setting for transplant-eligible patients.[11] Despite this recommendation, the regimen is an attractive option for some patients because it allows for a completely oral triple-drug combination. Similarly, ixazomib can be administered in combination with oral cyclophosphamide and dexamethasone. This may be beneficial in patients with renal dysfunction but lacks the supporting evidence associated with bortezomib-containing regimens. As discussed in a previous section, ixazomib combined with pomalidomide and dexamethasone is highly effective in patients experiencing early progression following two lines of IMiD and PI therapy. Table 159-4 lists the adverse drug reactions of ixazomib. Unlike carfilzomib, cardiac toxicity with ixazomib is minimal.[51]

Monoclonal Antibodies

⑦ Three monoclonal antibodies and one antibody-drug conjugate are FDA-approved for the treatment of MM. These monoclonal antibodies are often added to a combination drug regimen, with daratumumab incorporated into regimens for high-risk patients with MM.

Daratumumab

Daratumumab is an IgG1-κ fully human monoclonal antibody that targets CD38, a glycoprotein highly expressed on MM cells. Accelerated FDA approval for daratumumab in relapsed/refractory MM was granted after two open-label phase II trials of daratumumab showed single-agent activity (overall response rates of 29% and 36%).[52] Subsequent studies confirmed the role of daratumumab in combination therapy. A phase III trial of daratumumab, bortezomib, and dexamethasone reported a higher 12-month progression-free survival as compared to bortezomib and dexamethasone.[52] Similar findings were reported with daratumumab, lenalidomide, and dexamethasone, with a higher 12-month progression-free survival as compared with lenalidomide and dexamethasone.[52] Daratumumab, in combination with bortezomib, carfilzomib, lenalidomide, or pomalidomide and dexamethasone are NCCN category 1 recommendations for patients with relapsed and refractory MM.

Daratumumab combinations are also used in front-line therapy for newly diagnosed MM patients. The combination of daratumumab with bortezomib, melphalan, and prednisone was the first regimen approved for newly diagnosed, transplant-ineligible patients with MM. FDA approval was based on the phase III trial that showed that the addition of daratumumab to the regimen resulted in a higher overall response rate and a lower risk of disease progression and death as compared to bortezomib, melphalan, and prednisone.[53] Additional studies have reported the benefits of daratumumab combination therapy. The three-drug regimen of daratumumab, lenalidomide, and dexamethasone is considered a NCCN category 1 preferred recommendation as primary therapy for transplant-ineligible patients, and the four-drug regimen of daratumumab, bortezomib, thalidomide, and dexamethasone may be used as primary therapy for transplant eligible candidates.[11] Mayo Clinic mSMART guidelines recommend the four-drug regimen—daratumumab, lenalidomide, bortezomib, and dexamethasone—as initial treatment for patients with high-risk cytogenetics.[21]

Daratumumab is well-tolerated (Table 159-4). Infusion-reactions are common, occurring in 48% of patients.[53] Patients should be pre-medicated with a corticosteroid, acetaminophen, and an antihistamine to reduce the risk of a severe infusion reaction. Since daratumumab can interfere with cross-matching and red blood cell antibody screening, blood typing should occur before starting therapy.

Isatuximab-irfc

Isatuximab-irfc is a chimeric IgG-derived monoclonal antibody that also targets CD38 but at a different epitope than daratumumab. This leads to enhanced direct apoptosis without the need for effector cells or the complement system.[54] Isatuximab also inhibits the enzymatic activity of CD38 more effectively than daratumumab. This suggests more potent MM activity in vitro, although it is unknown if this will translate into increased clinical efficacy. Isatuximab may be active in patients who were refractory to daratumumab.[54] Isatuximab was initially approved in the third-line setting, following progression after lenalidomide and a PI, in combination with pomalidomide and dexamethasone. The combination with isatuximab showed improved response rates and progression-free survival over pomalidomide and dexamethasone alone.[55] Isatuximab is approved for patients who have received at least one prior line of therapy in combination with carfilzomib and dexamethasone. The adverse drug reaction profile of isatuximab is similar to that of daratumumab.

Elotuzumab

Elotuzumab is a monoclonal antibody directed against signaling lymphocyte activation molecule family 7 (SLAMF7), which is expressed on MM cells.[56] The binding of elotuzumab to SLAMF7 results in cytotoxicity through various mechanisms including antibody-dependent cellular cytotoxicity. Elotuzumab was evaluated in a phase III trial in combination with lenalidomide and dexamethasone in patients with relapsed and refractory MM. The elotuzumab combination improved progression-free survival and overall response rate as compared to lenalidomide and dexamethasone. Elotuzumab also improves progression-free survival when combined with either bortezomib or pomalidomide and dexamethasone. The elotuzumab, lenalidomide, and dexamethasone regimen is considered an NCCN category 1 recommendation for previously treated patients with MM.[11] Common adverse effects are listed in Table 159-4. Patients should be pre-medicated with dexamethasone, diphenhydramine, ranitidine, and acetaminophen to reduce the risk of an infusion reaction. Infusion reactions occurred in 10% of patients despite premedication, and most of the infusion reactions occurred with the first dose.[56] Patients receiving an elotuzumab-containing combination should also be monitored for infections because infections are the most common cause of non-myeloma-related death.

Belantamab mafodotin

Belantamab mafodotin is an antibody-drug conjugate targeting B cell maturation antigen (BCMA). Upon binding to BCMA, belantamab mafodotin is internalized and releases its monomethyl auristatin F (MMAF) payload, which inhibits microtubule formation.[57] Belantamab mafodotin is approved for patients who have received at least four prior lines of therapy, including a CD38 antibody, a PI, and an IMiD. The approval was based on the results of a phase II, DREAMM-2 study, in which belantamab mafodotin had an overall response rate of 31%.[57] Of those responders, nearly 75% of patients had a duration of response of 6 months or greater. The most common adverse drug reactions observed during the study were cytopenias, liver function test abnormalities, infusion reactions, and ocular toxicity, including vision loss. Due to the risk of ocular toxicity, belantamab mafodotin is only available through a restricted program under a Risk Evaluation and Mitigation Strategy (REMS). The REMS program requires the patient to undergo a thorough ophthalmic exam prior to each dose. Patients should use lubricating eye drops while on therapy and avoid the use of contact lenses.

Panobinostat

Panobinostat is an oral inhibitor of histone deacetylase enzymes and has shown activity in MM. Panobinostat was evaluated in a phase III trial in patients with refractory or relapsed MM who had received prior therapy with an IMiD and bortezomib.[58] Patients were randomized to receive bortezomib, dexamethasone, and panobinostat or bortezomib, dexamethasone, and placebo. The addition of panobinostat significantly improved progression-free survival.[58] No overall survival data have been reported. Adverse drug reactions are listed in Table 159-4. The regimen is considered an NCCN category 1 option for the treatment of relapsed/refractory MM who have received at least two prior therapies with an IMiD and bortezomib.[11]

Selinexor

Selinexor is the first in a new class of drugs that inhibits the nuclear export of tumor suppressor proteins (TSPs) and exportin 1 (XPO1).[59] The inhibition of XPO1 allows the cell to restore endogenous tumor suppressing proteins resulting in cancer cell apoptosis. Selinexor received accelerated FDA approval in 2019 for use with dexamethasone in patients with relapsed or refractory MM who have received at least four prior therapies, including an anti-CD38 monoclonal antibody (eg, daratumumab).[11] Serious adverse drug reactions are listed in Table 159-4. Following its initial approval, selinexor was combined with bortezomib and dexamethasone in patients progressing after at least one therapy, where the regimen showed an increase in progression-free survival compared to bortezomib and dexamethasone alone.[59] Weekly dosing of selinexor improves the tolerability of the drug, with less grade >3 hematologic toxicity when compared to twice weekly dosing.[59]

Melphalan Flufenamide

Melphalan flufenamide is a first-in-class peptide-drug conjugate, combining melphalan with a modified phenylalanine amino acid. The drug requires cleavage by an aminopeptidase for activation. Aminopeptidases are often overexpressed in malignant cells which allows for more targeted activity in MM cells. The FDA granted melphalan flufenamide, in combination with low-dose dexamethasone, accelerated approval for patients who have received at least four lines of therapy. The approval was based on a single-arm phase II trial that showed an overall response rate of 24%, with a median duration of response of 4.2 months.[60] Adverse drug reactions are listed in Table 159-4. While the phase III confirmatory study comparing melphalan flufenamide to pomalidomide and dexamethasone was being conducted, a significant increase in mortality was observed in patients receiving melphalan flufenamide. This caused the FDA to issue a safety warning in July 2021 and required the manufacturer to suspend all studies involving melphalan flufenamide pending further evaluation.[61]

Chimeric Antigen Receptor T-Cell Therapy

⑦ Chimeric antigen receptor (CAR) T-cell therapy is a novel form of immunotherapy in which a patient's T-cells are collected and genetically modified to target malignant cells. Multiple CAR T-cell products, directed at CD19, are FDA-approved for the treatment of B-cell malignancies. In 2021, the FDA-approved idecabtagene vicleucel for the treatment of relapsed or refractory MM after four or more prior lines of therapy, including an IMiD, a PI, and an anti-CD38 monoclonal antibody. The CAR T-cell product targets BCMA found on the surface of mature B lymphocytes and plasma cells. In the phase II trial that led to its approval, idecabtagene vicleucel showed an overall response rate of 73%, with 33% of patients achieving a complete response or better. MRD negative status was reached in 79% of those with a complete response.[62] In many cases, the responses are durable with a median progression-free survival of 19 months in patients achieving a complete response. Patients achieving a VGPR had a lower median progression-free survival of 10.4 months. These results are impressive considering the heavily pretreated patient population (median six lines of prior therapy, 95% prior autologous transplant). The most common adverse events observed were cytopenias, cytokine release syndrome (CRS), and immune effector cell-associated neurotoxicity syndrome (ICANS).[62] CRS is characterized by immune activation and release of inflammatory cytokines secondary to CAR T-cells interacting with target cells. CRS presentation can range from mild, flu-like symptoms to severe life-threatening organ dysfunction. CRS is treated with supportive care, tocilizumab (an interleukin-6 receptor antagonist), and steroids. The pathophysiology of ICANS is less completely understood but may be related to immune activation and vascular dysfunction. Similar to CRS, ICANS can present with a wide variety of symptoms, ranging from mild somnolence to cerebral edema and seizures. ICANS and CRS often present together but can occur independently. ICANS is treated with steroid therapy, antiepileptics, and other supportive care.[63] The NCCN has added idecabtagene vicleucel to its guidelines, but further studies are needed to determine its optimal place in therapy.

Initial Therapy

④ Initial therapy is guided by the NCCN, IMWG, ESMO, and mSMART recommendations and depends on whether the patient is symptomatic and a candidate for autologous HSCT (see Fig. 159-2). Eligibility factors for HSCT include patient age, renal function, performance status, and comorbidities. All patients with symptomatic MM are treated with primary therapy, with the selected regimen depending on transplant eligibility. Patients who are candidates for autologous HSCT will often receive 4 to 6 months of therapy before proceeding to hematopoietic stem cell collection, harvesting enough stem cells for two transplants.[11] Most patients will undergo autologous HSCT immediately following collection, but some patients may decide to delay the transplant until first relapse. Therapies that may compromise stem cell reserve are avoided in transplant-eligible patients. The selected regimen will often be composed of agents from multiple, distinct classes. Triplet combination regimens are commonly used and often include dexamethasone, a PI, and an IMiD. Patients who are not candidates for autologous HSCT usually continue their MM therapy or receive maintenance therapy, although the optimal duration of therapy after the desired response is achieved is unknown. Single-agent maintenance therapy, consisting of lenalidomide or bortezomib, may be given in both transplant-eligible and ineligible patients.

VRd is frequently used for primary therapy in both transplant-eligible and ineligible patients. Daratumumab, carfilzomib, or ixazomib-based therapy are additional treatment options for select patients. Treatment decisions are made based on physician preference, patient characteristics, and transplant eligibility. Some experts recommend a risk-adapted approach that personalizes treatment based on cytogenetics and gene expression profiling. The high cost of medications can pose a financial challenge for patients and clinicians who must consider the financial implications when selecting a regimen.

Some clinicians use a risk-adapted approach to select therapies (eg, mSMART). Bortezomib-containing induction regimens are recommended in patients with high-risk cytogenetics (see Fig. 159-2).[21] In this approach, high-risk patients receive a combination of daratumumab, bortezomib, lenalidomide, and dexamethasone as primary therapy. The combination of VRd is recommended in standard-risk patients. These regimens are continued in transplant-eligible patients for four cycles before transplant, but transplant can be delayed depending on patient preference. Transplant-ineligible patients will receive therapy for about 1 year and then possibly maintenance therapy. Lenalidomide- and bortezomib-based therapies may be used for maintenance therapy depending on risk.

⑤ A flow diagram shows the management of newly diagnosed myeloma. If the patient is transplant ineligible, there are two pathways. The first pathway is for patients with t(11;14), t(6;14), or trisomies, and is classified as standard risk. These patients should be treated with DVd or VRd for nine cycles, followed by lenalidomide maintenance until disease progression. The second pathway is for patients with t(4;14), t(14;16), t(14;20), or del17p and is classified as high risk. These patients should be treated with DVd or VRd for nine cycles, followed by bortezomib-based maintenance until progression. If the patient is transplant eligible, there are three pathways. The first pathway is for patients with t(11;14), t(6;14), or trisomies, and is classified as standard risk. These patients should be treated with four cycles of VRd, followed by stem cell collection. The patient then either proceeds with autologous transplant (preferred), followed by lenalidomide maintenance for a minimum of 2 years, or proceeds with four cycles of VRd, followed by lenalidomide until disease progression. The second pathway is for patients with Del17p, Gain 1q, t(4;14), or t(14;16) and is classified as high risk. These patients should be treated with four cycles of Dara-VRd followed by autologous transplant, and then bortezomib-based maintenance until progression. The third pathway is for patients with double or triple hit myeloma and is classified as high risk. These patients should be treated with four cycles of Dara-VRd followed by autologous transplant, and then bortezomib-based maintenance until progression.

Autologous Hematopoietic Stem Cell Transplantation

④ Although MM is a chemosensitive tumor with significant response rates after treatment with conventional chemotherapy, the duration of response is usually short. To improve outcomes with chemotherapy, high-dose chemotherapy regimens with autologous stem cell support is used after initial induction therapy. The intent of the induction therapy before transplant is to reduce tumor burden. With newer treatment regimens being used for induction, higher rates of quality responses (CR, VGPR, nCR) can be obtained which may improve the outcomes associated with autologous HSCT.

Randomized, controlled trials have evaluated the role of high-dose chemotherapy followed by autologous HSCT in patients with MM. Studies have confirmed that primary therapy followed by high-dose chemotherapy and autologous HSCT improves overall survival and increases complete response rates.[11,64] The timing of autologous HSCT has also been explored. An induction regimen of lenalidomide and dexamethasone followed by either chemotherapy (melphalan/prednisone/lenalidomide) or tandem melphalan-based autologous transplants was evaluated.[64] Results of this trial showed a progression-free survival and overall survival benefit for the autologous transplant arm. In a separate trial, patients received induction therapy with VRd, with either upfront or delayed consolidation with autologous HSCT, followed by lenalidomide maintenance therapy. Results of this trial showed that upfront transplant followed by maintenance resulted in significant improvements in progression-free survival but no difference in overall survival.[65] Based on available data, autologous HSCT improves response rates, symptom-free and progression-free survival but may not prolong overall survival. The lack of an overall survival advantage is likely due to improved salvage therapy. Despite this, current recommendations support high-dose chemotherapy and autologous HSCT in eligible patients with a first remission after primary therapy.[11,16,21]

The optimal timing of autologous HSCT (early vs late) in MM has also been investigated. In a landmark trial, patients were randomized to early (within 12 months of diagnosis) or late transplantation (>12 months after diagnosis), and no significant difference in 5-year overall survival was observed between the groups.[66] Event-free survival, however, was significantly longer in the early transplantation group (39 vs 13 months). In an analysis that factors in the time without symptoms, treatment, or treatment toxicity (TWiSTT), patients receiving early transplantation had a longer time in a state associated with a good quality of life (27.8 vs 22.3 months). The results of this study supported early autologous HSCT because of its effects on event-free survival and quality of life. Since then, two retrospective studies comparing early versus delayed autologous HSCT have been published.[67,68] These studies included MM patients who received an induction regimen that included either lenalidomide, thalidomide or another novel therapy. Both trials demonstrated similar time-to-progression and overall survival in the early (within 12 months) and delayed transplant groups. While most of the phase III trials have shown improvements in progression-free survival with transplantation, not all trials have shown an improvement in overall survival with transplantation.[69] This has been attributed to variations in primary treatment and study design. The collective results of these trials may support the idea that, in the setting of novel therapies, delaying transplant may be feasible for certain standard-risk patients, but the lack of rigorous, prospective, randomized data prevents the uniform recommendation to delay transplant. For patients with high-risk disease, current data do not support delaying transplant. Enrollment in clinical trials is highly recommended for most patients when evaluating the appropriate timing of HSCT in MM.[11]

A specialized form of autologous HSCT, tandem transplantation, involves the use of two separate autologous HSCT procedures separated by a rest period of several months. It was hypothesized that this more intensive approach would lead to improvements in therapeutic outcomes. Since the initial report of a benefit to the tandem transplant approach, several trials investigated this approach to therapy. Many of these trials were conducted before the availability of novel drugs and were shown to have conflicting results regarding overall survival.[69] Thus, the current data do not support the routine use of tandem transplants. Tandem autologous HSCT may be considered in selected patients with high-risk disease or those failing to achieve a VGPR after the first transplant, but any such decision would be best evaluated in the context of a clinical trial.[11,16,69]

The primary conclusion from the current data on autologous HSCT as consolidation therapy in MM is that it should be used in patients with good performance status. Advanced age and/or renal dysfunction should not be considered contraindications to transplant.[11] Before transplant, all patients should receive primary therapy to reduce tumor burden. Prolonged exposure to drugs such as lenalidomide and daratumumab can decrease the yield of stem cell harvest, so cells should be collected early on in therapy. Similarly, alkylating agents and nitrosoureas should be avoided before stem cell collection. NCCN recommends collecting sufficient hematopoietic stem cells for a second, salvage transplant in younger patients. The Mayo Clinic mSMART guidelines recommend autologous HSCT in transplant-eligible high-risk patients after the bortezomib-based induction therapy.[21] Standard-risk patients are given the option of autologous HSCT followed by maintenance therapy or continued induction followed by maintenance therapy (see Fig. 159-2).

Maintenance Therapy

⑧ Even with the advances in induction therapy and autologous HSCT, most patients will eventually progress within 3 to 5 years, suggesting that effective maintenance therapy could control or delay disease progression. Lenalidomide is frequently used as maintenance therapy in both transplant-ineligible and post-autologous HSCT patients with MM. Numerous trials have investigated the use of lenalidomide maintenance after autologous HSCT, showing improvements in progression-free and, possibly, overall survival compared to no maintenance therapy.[70] A 2017 meta-analysis examined the use of lenalidomide maintenance in newly diagnosed post-autologous HSCT patients with MM.[70] The analysis found significant benefits with lenalidomide maintenance compared to placebo or observation, extending median progression-free and overall survival.[70] While there are no direct head-to-head comparisons, a 2018 meta-analysis examined all regimens used for maintenance therapy and concluded that lenalidomide was the only maintenance therapy to improve progression-free and overall survival.[71] One unique adverse effect noted in these trials was second primary malignancy, including solid tumors, hematologic malignancies, and nonmelanoma skin cancers. These second malignancies occurred at a significantly higher rate as compared to placebo or control arms. Based on these data, the FDA issued a safety announcement to be added to the warning section of the lenalidomide drug labeling. Some practitioners advocate limiting the duration of maintenance lenalidomide to 2 years after transplant to minimize risk.[11]

Bortezomib may also be used for maintenance therapy in transplant-ineligible and post-autologous HSCT high-risk patients with MM. The 2018 meta-analysis of maintenance therapy showed that bortezomib-based therapies prolonged progression-free survival but did not improve overall survival.[71] Bortezomib is recommended over lenalidomide in the mSMART treatment and ESMO guidelines for maintenance therapy in high-risk patients.[16,21] Additionally, patients who do not achieve at least a VGPR after autologous transplant may benefit from bortezomib maintenance.[11]

Ixazomib has also been studied as maintenance therapy following autologous HSCT. The phase III TOURMALINE-MM3 trial randomized patients to oral ixazomib dosed on days 1, 8, and 15 in 28-day cycles or placebo as maintenance therapy for 2 years.[72] The trial showed that ixazomib maintenance therapy prolonged progression-free survival in newly diagnosed patients who received a single autologous HSCT within 12 months of diagnosis. While lenalidomide is the preferred maintenance medication by the NCCN guidelines, the guidelines added ixazomib as an option.[11] Since ixazomib is administered weekly, the convenient dosing may make it the preferred PI for maintenance therapy. The lack of secondary malignancies and low risk of peripheral neuropathy may make ixazomib a desirable alternative to lenalidomide. Future comparative trials are needed to determine the preferred maintenance therapy, particularly in patients with high-risk MM. The decision to use any of these agents in the maintenance setting must include careful consideration of the benefits and risks.

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic HSCT uses a stem cell source other than the patient and is therefore a transplant across immunologic barriers. Unlike autologous HSCT, which is simply a method of increasing the dose intensity of chemotherapy, allogeneic HSCT is a form of immunotherapy. The interest in allogeneic transplantation for MM is based on the use of a stem cell source free of tumor, which may potentially offer longer disease control and possible cure. The major posttransplant complications associated with allogeneic transplants are acute and chronic graft-versus-host disease (GVHD). GVHD may be accompanied by a graft-versus-myeloma effect. The graft-versus-myeloma effect, which is mediated by antitumor effector cells from the GVHD reaction, reduces relapse risk and may offer the patient the best chance for long-term disease-free survival.

Myeloablative allogeneic HSCT has traditionally been associated with high treatment-related mortality, between 20% and 60%.[73] Historically, allogeneic transplant has been used after patients have received and progressed after an autologous HSCT. Several trials have compared tandem autologous transplants to autologous followed by allogeneic stem cell transplant, although there is wide variability in trial design patient selection and protocols for the prevention and treatment of GVHD.[74] In all trials to date, no consistent improvement in overall survival or progression-free survival has been reported. Meta-analyses show that allogeneic HSCT may result in a higher CR rate, including long term remissions, but this comes at the cost of a higher rate of transplant-related mortality.[11]

Allogeneic HSCT may have a role in the management of patients with high-risk disease. Ongoing clinical trials are evaluating the role of allogeneic HSCT in patients with MM who have high-risk cytogenetic characteristics, who are not likely to respond to upfront therapy or who relapse quickly after upfront therapy or autologous HSCT. There is increasing interest in the use of reduced-intensity conditioning regimens. Based on the available data, upfront myeloablative allogeneic HSCT is not routinely recommended.

Relapsed or Refractory Disease

⑨ The most appropriate therapy for an individual who relapses depends on the type and duration of previous therapies, whether the patient received a transplant, presence or absence of adverse prognostic factors, toxicity of prior therapies (eg, peripheral neuropathy), organ dysfunction (eg, renal impairment), and how much time has elapsed from initial response to relapse.[11] The same drugs used to treat MM initially can also be used as salvage therapy in patients who have relapsed more than 6 months after primary induction therapy.[11] Patients with relapsed or refractory MM can be treated with active agents in combination or single agents used sequentially. With the growing number of highly active agents, combination therapy is more commonly given. There are no direct comparisons of the frequently utilized regimens for relapsed and refractory disease making it difficult to determine the best treatment option. The NCCN has seventeen category 1 recommendations (13 triplet and 4 doublet regimens) and lists many other additional regimens.[11] Combination therapy continues to incorporate a PI, IMiD, and dexamethasone. Daratumumab, elotuzumab, and isatximab-irfc may also be used in various regimens. A systematic review suggests the combination of daratumumab, lenalidomide, and dexamethasone may be superior in patients with progressive disease.[75] Other meta-analyses have reported triplet-based combinations with monoclonal antibodies are superior (extending progression-free survival) compared to other regimens in patients with relapsed and refractory disease.[76] CAR T-cell therapy with idecabtagene vicleucel has reported encouraging results and may be considered in patients who have progressed after multiple lines of therapy. Despite clear progress, most salvage therapies produce less than a 50% response rate, and new drugs and drug combinations are needed.

Questions remain on the optimal timing for autologous HSCT. For patients who are eligible for autologous HSCT and did not receive a transplant as part of initial therapy, autologous HSCT should be considered at first relapse. Autologous HSCT in first remission trends toward longer progression-free survival compared to those transplanted beyond first remission.[77] Salvage autologous HSCT may be beneficial in patients who were heavily pretreated and refractory to daratumumab.[78] The role of salvage autologous transplant may continue to be minimized with the approval of additional drugs and the use of maintenance therapy.

Supportive Care

Bone-Modifying Agents

⑩ Along with anti-MM therapy, supportive care measures are aggressively used to stabilize skeletal abnormalities. Patients with MM have a high rate of bone involvement. The mechanism of MM-associated bone disease is thought to be mediated through several pathways, including IL-6, IL-1, and TNF-α, but the most targeted pathway is that involving receptor activator factor kappa B ligand (RANK-L) and osteoprotegerin (OPG).[23] Skeletal homeostasis is complex. In normal bone, RANK-L and OPG are both produced by osteoblasts. RANK-L binds to RANK receptors on osteoclasts, to stimulate bone resorption, and to OPG, a “decoy receptor,” to inhibit bone resorption and stimulate bone formation. A balance between RANK-L and OPG is the basis for normal bone remodeling. In MM, an imbalance in normal bone homeostasis leads to increased osteoclast activity and the formation of osteolytic bone lesions which can lead to clinically significant skeletal-related events, including fracture, hypercalcemia, and bone pain. Based on the 2019 ASCO guidelines, clinical indications for bone modifying therapies include hypercalcemia, renal dysfunction, anemia, and bone disease. In the absence of these features, patients with >60% plasma cells in the bone marrow or more than one site of bone disease are now recommended for treatment.[79] The NCCN guidelines recommend bone modifying therapies for all patients regardless of documented bone disease. Preventative therapies are initiated early to delay myeloma bone disease. Myeloma bone modifying therapies should be continued for at least 2 years with discontinuation based on clinical judgment.[11]

The primary therapies for the prevention of myeloma bone disease include antiresorptive bisphosphonates (ie, zoledronic acid and pamidronate) and denosumab. Bisphosphonates bind to hydroxyapatite and are incorporated into the bone matrix, suppressing osteoclast activity.[80] There are two classes of bisphosphonates (ie, nitrogen and non-nitrogen containing) based on their binding affinity with hydroxyapatite. The nitrogen-containing bisphosphonates of zoledronic acid and pamidronate are 100 to 10,000 fold more potent than the non-nitrogen containing bisphosphonates (ie, etidronate).[80] For this reason, zoledronic acid and pamidronate are used in the management of myeloma bone disease. Bisphosphonates may also promote apoptosis in MM cells, modify the cytokine microenvironment, inhibit the adhesion of MM cells to bone marrow matrix cells, and inhibit angiogenesis.[81] A meta-analysis in patients with MM shows bisphosphonates reduce pain, overall fractures, and fractures of the vertebrae.[80]

Pamidronate and zoledronic acid are usually well tolerated. Acute-phase reactions consisting of flu-like symptoms can occur after the administration of bisphosphonates. Acute renal impairment can occur with both agents and is related to both infusion time and dose. Patients with moderate renal impairment (creatinine clearance: 30-60 mL/min [0.5-1.0 mL/s]) require renal dose adjustments of zoledronic acid, and the use of zoledronic acid is not recommended in patients with severe renal impairment.[82] This is important as patients with MM often have renal dysfunction. Osteonecrosis of the jaw (ONJ) is a serious adverse effect of bisphosphonates. ONJ is characterized by an area of exposed necrotic bone and often affects the mandible and the maxilla, but it can also affect the soft palate. The development of ONJ may be related to dental disease and tooth extraction, dependent on the dose and duration, and is more common with IV bisphosphonates (vs oral) and zoledronic acid (vs pamidronate).[79] The incidence of ONJ is unknown but may be as high as 10% in MM patients receiving zoledronic acid for extended periods. A meta-analysis found no difference between the bisphosphonate used and the incidence of ONJ.[83] Patients should be advised to have dental work completed before the initiation of bisphosphonates, if possible.

Denosumab has also been shown to reduce the incidence of myeloma skeletal-related events and is used in the prevention of myeloma bone disease. Denosumab is a monoclonal antibody directed toward RANK-L. By binding to RANK-L, denosumab prevents binding of RANK-L to RANK, reducing osteoclast activity and allowing bone formation and osteoblast function to predominate. A phase III trial evaluated the efficacy and safety of denosumab compared to zoledronic acid in patients with newly diagnosed MM.[84] Results from this study found denosumab to be noninferior to zoledronic acid in delaying time to first skeletal-related event. Rates of overall survival and ONJ were similar between groups. In an exploratory analysis of an international phase III study, denosumab showed an increase in median progression-free survival compared to zoledronic acid, which suggests that denosumab may have antimyeloma activity.[85] The results were most favorable in the subset of patients who had received PI-based triple therapy and were transplant eligible. While the risk of ONJ with denosumab and zoledronic acid is similar, the risk of renal adverse effects is higher with zoledronic acid.[84] The NCCN guidelines recommend denosumab for patients with renal disease because denosumab does not worsen renal function or require dose adjustments with renal impairment.[11]

EVALUATION OF THERAPEUTIC OUTCOMES

The goals of therapy are to prolong survival and improve quality of life. Patients with asymptomatic MM are usually observed and not treated. Asymptomatic patients are assessed every 3 to 6 months for disease progression, which would then warrant therapy. Assessment involves measurement of M protein in blood and urine and laboratory tests that include complete blood count, serum creatinine, and calcium. Patients are treated as the disease produces symptoms. Disease response is defined by a decline in M protein. After completion of the initial course of therapy and once a response is obtained, patients should be monitored every 3 months. NCCN guidelines have been updated to include assessment of MRD status after treatment. Bone surveys are performed yearly or as required because of changes in symptoms. Various other tests, including bone marrow biopsy, magnetic resonance imaging, and positron emission tomography, or computed tomography scan, are performed as needed to evaluate disease status.

CONCLUSION

MM is a cancer that occurs due to the abnormal proliferation of plasma cells. Hallmark symptoms are associated with the acronyms CRAB. While MM is an incurable disease, novel drug classes have improved response rates and overall survival compared to conventional chemotherapeutic agents. Triple regimens are often used and include dexamethasone, a PI, and an IMiD. Autologous HSCT plays a role in patients who are transplant eligible. Unfortunately, most patients will eventually experience refractory/relapsed disease where multiple agents and classes of drugs may be utilized to manage disease progression. To improve quality of life, clinicians should address and manage disease symptoms and adverse effects. Future advances in the treatment of MM depend on a better understanding of the pathophysiology of MM, identification of new drug targets, and development of new drugs.

ABBREVIATIONS

ASCO	American Society of Clinical Oncology
CAR	chimeric antigen receptor
CI	confidence interval
CR	complete remission
CRS	cytokine release syndrome
HSCT	hematopoietic stem cell transplantation
ICANS	immune effector cell-associated neurotoxicity syndrome

SELF-ASSESSMENT QUESTIONS

1. Multiple myeloma is a malignancy involving which cell type?

   A. Platelets

   B. Lymphoid

   C. Plasma

   D. Myeloid

2. Which features are characteristics of myeloid-related events and suggest end-organ damage?

   A. Bone involvement, anemia, and renal insufficiency

   B. Hyperbilirubinemia, increased serum creatinine, and anemia

   C. Thrombocytopenia, hypoalbuminemia, and bone involvement

   D. Lymphocytosis, hypogammaglobulinemia, renal insufficiency

3. DM is a 57-year-old male who presents to his primary care provider for his annual well-check. He reports feeling great and he does not have any concerns. His physical assessment is unremarkable. Routine labs are drawn, and the result of his serum protein electrophoresis profile reveals 3.8 g/dL (38 g/L) monoclonal immunoglobulin in the blood. Further work-up from a bone marrow biopsy shows 30% clonal plasma cells, suggestive of smoldering myeloma. What is the recommended approach?

   A. Autologous HSCT

   B. Primary therapy with bortezomib, lenalidomide, and dexamethasone

   C. Maintenance therapy with lenalidomide

   D. Observation

4. SB is a 78-year-old female with newly diagnosed multiple myeloma. She is meeting today with her oncologist to discuss possible treatment options. SB is unable to drive and has concerns about finding rides for her appointments this winter. Which regimen consists of all oral agents, alleviating the need to travel to the infusion center?

   A. Bortezomib, lenalidomide, dexamethasone

   B. Carfilzomib, lenalidomide, dexamethasone

   C. Daratumumab, bortezomib, melphalan, prednisone

   D. Ixazomib, lenalidomide, dexamethasone

5. WR is a 52-year-old male who was recently diagnosed with high-risk multiple myeloma. Based on the risk-adapted mSMART approach, what induction regimen is preferred for WR?

   A. Cyclophosphamide, bortezomib, melphalan, dexamethasone

B. Daratumumab, bortezomib, lenalidomide, dexamethasone

C. Elotuzumab, lenalidomide, dexamethasone

D. Panobinostat, carfilzomib, melphalan, prednisone

6. The preferred method of bortezomib administration is:

A. Continuous infusion

B. Intramuscular

C. Oral

D. Subcutaneous

7. A 66-year-old man is receiving ixazomib as part of his treatment regimen for multiple myeloma. Which of the following supportive medications is recommended?

A. Antibacterial prophylaxis with levofloxacin

B. Antifungal prophylaxis with fluconazole

C. Antiviral prophylaxis with valacyclovir

D. Antibacterial prophylaxis with Bactrim DS

8. Which drug is associated with cardiac and pulmonary toxicities warranting close monitoring and assessment?

A. Lenalidomide

B. Elotuzumab

C. Carfilzomib

D. Daratumumab

9. What is the optimal timing for autologous HSCT in patients with multiple myeloma?

A. No role for autologous HSCT

B. At the point of disease relapse following first-line therapy

C. Following induction therapy, within 12 months of diagnosis

D. At the point of disease relapse after failing first- and second-line therapy

10. Which of the following patients is the BEST candidate for autologous stem cell transplantation for multiple myeloma?

A. An 82-year-old man who has received six cycles of induction therapy, complicated by sepsis and renal failure, is now in a complete response. He has ongoing significant renal insufficiency, mild dementia, and uncontrolled hypertension.

B. A 54-year-old man who has received six cycles of induction therapy with refractory disease. No other significant comorbidities.

C. A 73-year-old woman who completed six cycles of induction therapy, achieved a complete response, underwent an autologous stem cell transplant 4 months ago and has relapsed. She is receiving reinduction therapy cycle 2, with a partial response.

D. A 62-year-old woman who has completed 6 months of induction therapy and is in a very good partial response. She has a past medical history of

Type II diabetes, controlled with oral medications, and obesity.

11. Which agent would be most appropriate in the maintenance setting for a patient experiencing significant peripheral neuropathy following induction therapy and autologous stem cell transplant?

    A. Thalidomide

    B. Carfilzomib

    C. Ixazomib

    D. Bortezomib

12. When should allogeneic stem cell transplantation be used in patients with myeloma?

    A. Upon failure of at least two prior autologous transplants

    B. For patients under the age of 50 years with aggressive disease

    C. For all patients under 60 years, due to the benefits of graft versus myeloma

    D. Only in the context of a clinical trial

13. Which of the following adverse effects are associated with idecabtagene vicleucel treatment?

    A. Cardiotoxicity

    B. Cytokine release syndrome

    C. Ocular toxicity

    D. Peripheral neuropathy

14. LL is a 58-year-old receiving VRd for multiple myeloma. He has a past medical history of a pulmonary embolism and is considered high risk for thrombosis. What is the most appropriate venous thromboembolic agent?

    A. Aspirin

    B. Apixaban

    C. Clopidogrel

    D. Heparin

15. CS is a 57-year old with newly diagnosed MM. Her renal function is 45 mL/min (0.75 mL/s). Which is the best bone modifying agent for the prevention of skeletal-related events?

    A. Pamidronate

    B. Zoledronic acid

    C. Denosumab

    D. Calcium carbonate

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** MM is characterized by the accumulation of malignant plasma cells in the bone marrow.
2. **A.** Hypercalcemia, renal insufficiency, anemia, and bone lesions (acronym *CRAB*) are considered myeloma-defining events, and suggest end-organ damage.
3. **D.** Patients with smoldering myeloma are asymptomatic and do not warrant immediate pharmacotherapeutic treatment. Instead, the disease should be observed (watchful waiting) unless the patient is considered high-risk.
4. **D.** Ixazomib is an oral proteasome inhibitor. Thus, ixazomib, lenalidomide, dexamethasone is a completely oral triple-drug oral regimen.
5. **D.** The four-drug regimen of daratumumab, bortezomib, lenalidomide, and dexamethasone is preferred for high risk, transplant-eligible patients per mSMART guidelines. Bortezomib-based therapy is preferred for patients with high-risk characteristics determined by the mSMART criteria.
6. **D.** Subcutaneous bortezomib is more convenient and has a reduced incidence of peripheral neuropathy over intravenous bortezomib.
7. **C.** Antiviral prophylaxis against the herpes virus is recommended for patients receiving proteasome inhibitors.
8. **C.** Carfilzomib is associated with cardiac and pulmonary toxicities, including hypertension and dyspnea.
9. **C.** Available literature supports the use of autologous stem cell transplantation in patients with myeloma in their first remission, within 12 months of the completion of induction therapy. Remission does not need to be a complete remission but should represent a significant response to therapy (PR, VGPR, or CR). Patients with disease refractory to induction therapy are unlikely to benefit from transplant. Waiting to transplant until after relapse is associated with poorer outcomes when compared to transplant in first response.
10. **D.** Autologous stem cell transplant is a rigorous treatment modality that provides the best result in patients with myeloma who are in their first remission, and who have either no or few uncontrolled comorbidities. Patients who are older or have uncontrolled comorbidities, poor performance status, or fail to respond to induction therapy are unlikely to derive clinical benefit from the autologous transplant, and may experience more severe toxicities from therapy.
11. **C.** Lenalidomide, bortezomib, and ixazomib are all approved in the maintenance setting. Thalidomide and carfilzomib are not indicated for maintenance. Bortezomib and ixazomib can be used for maintenance; however, bortezomib could potentially worsen the patient’s neuropathy.
12. **D.** Allogeneic stem cell transplant has limited utility in myeloma, except in cases of relapsed disease in young patients with good performance status. The risks of allogeneic transplant usually outweigh the benefits. To better understand the potential utility of this modality of therapy, it is recommended that patients considered for allogeneic transplant be referred to centers conducting clinical trials to determine the optimal use in myeloma.
13. **B.** Cytokine release syndrome is a common complication of CAR T-cell therapy. Cardiotoxicity is most associated with carfilzomib. Belantamab mafodotin has been shown to cause reversible ocular damage. Neuropathy is associated with PI therapy.
14. **B.** Therapeutic anticoagulation is warranted for patients who have a high risk of thrombosis and are receiving immunomodulatory therapy. The combination of dexamethasone with lenalidomide further increases the risk of a venous thromboembolic event. Anticoagulation with a direct oral anticoagulant is a reasonable choice for this patient. Other options would include warfarin or LMWH.
15. **C.** Both zoledronic acid and denosumab reduce the risk of skeletal complications of myeloma. Zoledronic acid, however, requires dose adjustments for mild-to-moderate renal dysfunction and is not recommended in patients with severe dysfunction. In these settings, denosumab is the preferred agent because it does not require dose adjustment for renal dysfunction and has comparable efficacy to bisphosphonates.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 162: Melanoma

Cindy L. O'Bryant; Christina M. Davis

KEY CONCEPTS

KEY CONCEPTS

1 Cutaneous melanoma is an increasingly common malignancy that can be cured if detected early. Public education about screening and early detection is one strategy to reduce the mortality associated with cutaneous melanoma.

2 Surgical resection can cure patients with early-stage melanoma.

3 Adjuvant therapy should be considered in patients with locally advanced disease; recommended options include ipilimumab, nivolumab, pembrolizumab, BRAF and MEK inhibitors, and clinical trial.

4 Chemotherapy and biochemotherapy offer limited benefit in the treatment of metastatic melanoma.

5 Immunotherapy with ipilimumab, nivolumab, the combination of ipilimumab/nivolumab and pembrolizumab have led to durable responses and significantly prolonged overall survival in patients with metastatic melanoma.

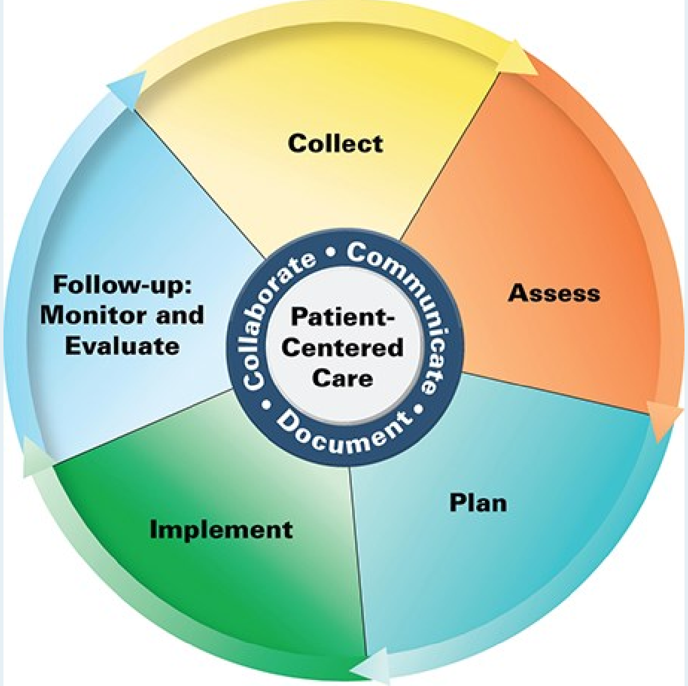
6 Immune-related toxicities associated with immunotherapy can be severe and life-threatening. Consequently, the use of these agents warrants appropriate patient selection, close monitoring, and toxicity management by an experienced healthcare team.

7 As the biology of melanoma has been further delineated, a growing number of potential targets for drug therapy have been identified. *BRAF* mutations occur in up to 70% of melanoma patients. The combination of BRAF and MEK inhibitors improves overall survival in patients with this mutation.

8 Treatment of melanoma is determined by many factors. As the number of treatment options for patients with metastatic melanoma grows, disease- and patient-related factors should be considered when determining appropriate therapy.

PATIENT CARE PROCESS

Patient Care Process for Melanoma



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, physical features)
- Patient medical history (personal/family) including autoimmune diseases
- Social history (eg, history of blistering sunburns; intermittent, intense sun exposure; tanning bed use)
- Current medications including OTC products, herbal products, dietary supplements, current or past use of immunosuppressants
- Objective data
  - Type of biopsy performed
  - Pathology report: Breslow thickness, presence or absence of ulceration, mitotic rate
  - Routine imaging and labs not recommended for early stage/localized disease; perform for baseline staging in stage IIIB or higher (can be considered for stage IIIA)
  - Labs: serum creatinine (SCr), liver function (AST, ALT, total bilirubin), lactate dehydrogenase (LDH), complete blood count (CBC), thyroid function (TSH, free T4) for regional/metastatic disease

Assess

- Appropriate primary treatment (wide excision, need for sentinel lymph node biopsy)
- Status of sentinel lymph node biopsy (if performed); if positive sentinel lymph node, appropriateness of nodal basin ultrasound surveillance versus complete lymph node dissection
- Mutational analysis, if appropriate
- Presence of active autoimmune disease
- Ability/willingness to complete 1 year of adjuvant treatment, if recommended

- Ability/willingness to pay for treatment options
- Ability/willingness to obtain laboratory monitoring tests and imaging to evaluate signs and symptoms
- Emotional status (eg, presence of anxiety, depression)

Plan

- Wide excision for all stages. Consider sentinel lymph node biopsy for stage IB; offer to stage II
- Adjuvant treatment with either PD-1 inhibitor or BRAF and MEK inhibitor combination for patients with fully resected stage III or stage IV disease that are appropriate for therapy
- Drug therapy regimen including specific drug(s) dose, route, frequency, and duration (see Tables 162-7 and 162-8)
- Referral to neurosurgery for treatment of brain metastases (Gamma Knife stereotactic radiosurgery; resection by craniotomy)
- Monitoring parameters including efficacy (eg, CT and brain MRI as indicated) and safety (eg, signs and symptoms of immune-related adverse events [irAEs]); frequency and timing of follow-up
- Patient education (eg, purpose of treatment, drug-specific information, proper administration/storage/handling for targeted therapies, when to seek emergency medical attention; see Tables 162-7 to 162-10)
- Referrals to other specialists when appropriate (eg, endocrinology, GI)

Implement*

- Provide patient education regarding all elements of the treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-up: Monitor and Evaluate

- At least annual skin examination; self-examination of skin and lymph node
- Imaging to assess signs/symptoms and/or every 3 to 12 months to screen for recurrence
- Presence of adverse drug reactions
- Patient adherence to treatment plan using multiple sources of information

**Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

Review educational materials regarding skin self-examinations created by the American Cancer Society (https://www.cancer.org/healthy/be-safe-in-sun/skin-exams.html) and the American Academy of Dermatology Association (https://www.aad.org/public/diseases/skin-cancer/find/check-skin). Assess the level of understanding and ease of use from a patient perspective for each. Then perform your own skin self-examination based on the ABCDE rule to identify any new or suspicious spots on your skin. This activity will enhance student understanding regarding the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION

Skin cancer is the most common malignancy worldwide and is associated with chronic ultraviolet (UV) exposure. The two types of skin cancer are nonmelanoma skin cancers (NMSCs) and melanoma. Although NMSCs are the most common malignancy of the skin, cutaneous melanoma accounts for up to 80% of all skin cancer-related deaths.[1] Melanoma cases are increasing globally with the highest rates found in Australia, New Zealand, North America, and Northern Europe.[2] Melanoma is the fifth most common cancer in the United States.[1] The incidence of melanoma has rapidly increased in the United States over the last 30 years, and has increased an average of 1.4% each year over the last decade.[3] When detected early, patients generally have a good prognosis. Skin cancer prevention and screening have a major impact on public health and the success of treatment for those individuals diagnosed with NMSC and melanoma. Skin cancers tend to occur more frequently in older individuals with a median age of diagnosis of 65 years.[3] Therefore, as the population continues to age, effective strategies to prevent, detect, and treat individuals with these cancers are necessary. An understanding of the biology of melanoma has led to the development of therapies targeted toward somatic mutations and the immune response, which have shown improved outcomes in patients with advanced melanoma.

EPIDEMIOLOGY

In the United States, it is estimated that 99,780 cases of melanoma will be diagnosed in 2022, accounting for 7,650 deaths.[4] The overall incidence is greater in men than women, but rates are higher in women before the age of 50. Risk also varies with ethnicity, with most melanoma cases occurring among White individuals.[4] Childhood and adolescent melanoma account for only 1% and 3%, respectively, of new melanoma cases each year but is the most common skin cancer in individuals younger than 20 years.[5] The majority of childhood and adolescent melanoma occurs in females and non-Hispanic White patients.[6] From the 1970s to the early 2000s, the incidence of melanoma in those younger than 20 years increased by 2% to 3% per year, but data from 2004 to 2010 show a decrease of 11.6% per year.[6]

Survival rates for patients with melanoma have gradually increased over the past four decades. Due to recent advances in treatment, the five-year relative survival rate is 93.3% for all stages of melanoma, but survival declines to 29.8% in patients with more advanced disease.[3] Over the last decade, the death rate from melanoma has declined around 1% per year in adults older than 50 years and 3% per year in adults younger than 50 years.[3]

Several patient-specific and environmental risk factors have been identified (see Table 162-1), and it is likely these factors alone, or in combination, increase the risk of cutaneous melanoma.

TABLE 162-1

Risk Factors for Melanoma

Patient-Specific Risk Factors
Adulthood (older than 15 years) History of cutaneous melanoma Dysplastic nevi High density of common nevi and atypical nevi Cutaneous melanoma in first-degree relative Immunodeficiency or immunosuppression High degree of freckling Sunburns easily or tans rarely Blonde or red hair Blue, green, or gray eyes Socioeconomic status (higher > lower) Race (Caucasians > Hispanics > African Americans)
External Risk Factors
Intense, intermittent sun exposures History of sunburn More than four painful sunburns before the age of 15 years Recreational sun exposure

Both UVB and UVA are known carcinogens and are related to the development of melanoma. Caucasian individuals with fair-colored hair (red or blond), light-colored eyes (blue or green), high degrees of freckling, and those who tend to burn and rarely tan with sun exposure, are especially at risk. Clinical and epidemiologic research shows a higher rate of melanoma in those who have extensive or repeated intense UV and sun exposure.[1] Intermittent, intense sun exposure, blistering sunburns, tanning bed use, and the time of life when exposed to the sun are critical factors for the development of cutaneous melanoma.[7,8] The risk of melanoma seems to be greater during childhood and adolescence due to sunlight and UV radiation exposure and lower in adults who have had chronic sun exposure, are without a history of burning, and those with occupational exposure.

A significant risk factor for melanoma is the number and size of melanocytic nevi (pigmented lesions or moles) on the body. The formation of these nevi is directly related to cumulative sun exposure. The relative risk of developing melanoma increases with the number of typical nevi on an individual. A second risk factor is the presence of atypical melanocytic nevi. Atypical nevi may progress from a normal nevus or be dysplastic from the onset. Up to 20% of melanomas develop from atypical nevi. Congenital melanocytic nevi may be present at birth or within the first few months of life, and the associated risk of melanoma increases with size.[1,6]

Other risk factors in the development of melanoma include immunodeficiency (either inherited or acquired), a personal history of NMSC or melanoma skin cancer, and a diagnosis of xeroderma pigmentosum, a rare skin disorder. Patients with these risk factors often have more aggressive disease and have been shown to have a poor prognosis.[1,6]

Family history is associated with up to 10% of cases of melanoma. Familial atypical multiple mole syndrome (FAMMM) or dysplastic nevus syndrome is an autosomal dominant hereditary disease that accounts for about 1% of melanoma cases. It is characterized by the presence of numerous common and atypical moles and a family history of melanoma in multiple first-degree relatives and younger age at diagnosis.[9,10] Patients with FAMMM syndrome are at considerable risk for developing melanoma which increases with age. FAMMM syndrome is associated with mutations in the *CDKN2A* gene. *CDKN2A* encodes two distinct proteins: p16, an inhibitor of cyclin-dependent kinase 4 and 6, and p14ARF, which inhibits p53 degradation.

Mutations in *CDKN2A* result in increased proliferation and decreased apoptosis.[9,10]

ETIOLOGY

Melanoma arises from the melanocytes in the basal layer of the epidermis. DNA damage, most commonly a result of UV radiation, leads to cellular mutations that transform the cell and result in uncontrolled proliferation and the formation of tumors. The identification of these genetic alterations has led to the recognition of molecular subgroups of melanoma and more focused drug development for treatment.

A major signaling pathway associated with the development of melanoma is the mitogen-activated protein kinase pathway (MAPK), which mediates receptor tyrosine kinases, resulting in activation of RAS and downstream BRAF. Activating *BRAF* mutations are the most common somatic genetic event in human melanoma, occurring in about 50% of melanoma patients and primarily noted by a single point mutation at residue V600. The V600E mutation, in which valine is substituted for glutamic acid at codon 600, is the most common point mutation. The V600K mutation may also occur at this residue. *BRAF* mutations are associated with younger age at diagnosis, intermittent sun exposure, and superficial spreading melanoma.[10]

Upstream of BRAF, mutations in *NRAS,* and c-*Kit* can act as molecular drivers in the development of melanoma. Mutations in *NRAS* are found in up to 20% of patients. These tumors are associated with chronic sun exposure and high growth rates.[7] *KIT* is a transmembrane receptor tyrosine kinase that, when activated, signals the MAPK and phosphatidyl-inositol-3-OH kinase (PI3K) pathways, resulting in transcription and cell proliferation. Mutations in *KIT* are commonly found in acral and mucosal melanomas as well as those with chronic sun exposure.[10]

Other genetic alterations involved in the development of melanoma include *MITF* (microphthalmia-associated transcription factor) and *MCIR* (melanocortin 1 receptor gene). *MITF* is a gene important to the survival of melanocytes and, when mutated, acts as an oncogene. *MCIR* is prevalent in individuals with melanoma and signals through the MITF pathway. It is involved in melanin synthesis and is associated with the red hair and fair skin phenotype.[10]

PATHOPHYSIOLOGY

Melanomas most often arise within epidermal melanocytes of the skin, although they can also arise from non-cutaneous melanocytes. During fetal development, melanocytes migrate over a predictable route to multiple sites within the body, including the skin, uveal tract, meninges, and ectodermal mucosa. Melanocytes synthesize melanin to protect various tissues, such as the skin, from UV damage and reach the keratinocytes in the upper layers of the epidermis via dendrites. Primary melanoma can arise in any area of the body with melanocytes. Cutaneous melanoma is the most frequent site constituting 90% of all melanomas. Other sites of primary melanoma include the eye (uveal melanoma), the mucosa, and in some cases, as metastatic disease with an unknown primary site.[10]

The pathogenesis of human melanoma involves a series of morphologic stages: melanocytic atypia, atypical melanocytic hyperplasia, radial growth phase, vertical growth phase with or without in-transit metastasis, regional lymph node metastatic melanoma, and distant metastatic melanoma. Melanoma gains the potential for metastasis with the onset of a vertical growth phase. Therefore, the thickness of a primary melanoma is an important prognostic factor and is used in the staging classification of cutaneous melanoma. As the disease progresses, melanoma cells increase the production of certain growth factors and cytokines which, in turn, activate cellular growth and survival pathways, including the MAPK, PI3K/AKT, and mammalian target of rapamycin (mTOR). Understanding the biology of melanoma has provided targets for innovative drug therapy.

The role of the immune system in the development of melanoma is well documented and spontaneous cancer regressions associated with host immunity have been reported.[11] Melanoma cells evade the immune system by exploiting immune checkpoints. Immune checkpoint receptors such as cytotoxic T-lymphocyte antigen 4 (CTLA-4) and programmed death-1 (PD-1) are found on the surface of activated T cells and, when bound to a ligand, inhibit the function of the T cell. In the case of PD-1, when interferon is released by T-cell recognition of the melanoma cell, janus-kinase (JAK) and signal-transducer-and-activator-of-transcription (STAT) are upregulated, leading to increased expression of programmed cell death ligand 1 (PD-L1) on the melanoma cell surface. When PD-L1 binds to PD-1, the T cell becomes inactivated and the antitumor immune response is inhibited.[7]

MELANOMA SUBTYPES

Histologic

Cutaneous melanomas are categorized by growth patterns. Four major histologic subtypes, or growth patterns of primary cutaneous melanoma, have been identified: superficial spreading melanoma (SSM), nodular melanoma (NM), lentigo maligna melanoma (LMM), and acral lentiginous melanoma (ALM). While these subtypes do not directly correlate with clinical outcomes, certain subtypes have been shown to demonstrate a higher frequency of genetic mutations.

SSM is the most common type of cutaneous melanoma, accounting for up to 70% of all melanomas and is associated with intense, intermittent sun exposure. Early in lesion development, SSM is flat, growing radially before vertically. SSM evolves slowly, typically over 1 to 5 years. As the lesion progresses, it may become raised or ulcerated. The borders are often irregular and asymmetrical as the lesion progresses and may vary in color (blue, black, brown, pink, or other colors). SSMs may occur at any anatomic site on the body but are more commonly found on the trunk and extremities. The average age of a diagnosis of SSM is 50 years. These lesions can be linked to mutations in *BRAF*.

Nodular melanoma is the second most common histological type of melanoma, occurring in 15% to 30% of patients. Since nodular melanoma is a pure vertical growth phase disease, it is more aggressive and develops more rapidly than other subtypes.[10] Nodular melanomas are often dark blue–black and uniform in color with a shiny surface, although a small percentage of nodular melanomas are amelanotic and have a fleshy appearance. Nodular melanomas are raised, often symmetric, and can occur at any site. *LMM* represents 10% to 20% of melanomas and is commonly found on the head and neck. It is unique from other histologic subtypes; it does not have the same propensity to metastasize because of a prolonged radial growth phase. LMM arises on chronically sun-exposed sites in older individuals and presents as a freckle-like lesion. LMMs are generally large flat, tan-colored lesions with shades of brown and black that gradually grow, develop, and begin to change in color.[10] Evolution into invasive melanoma is characterized by nodular development within the flat lesion. These lesions can be linked to mutations in *KIT*.

ALM makes up about 5% of melanomas and is not related to UV exposure. It presents commonly as melanoma on the palms of the hands or soles of the feet but may present as subungual melanoma and mucosal melanoma. ALMs located on the soles of the feet appear as a large tan or brown stain. The lesions often have irregular convoluted borders and may be masked by thick skin on the feet. Subungual melanoma arises in the nail matrix or nail bed. The most common presentation is a brown or black line in the great toe or the thumbnail. Mucosal melanoma is rare and can occur on any mucosal surface. Most commonly is seen in the oropharyngeal mucosa followed by the anal and rectal, genital, and urinary mucosa. Unfortunately, mucosal melanoma often does not become clinically apparent until the mass is large or the lesion bleeds. ALM is the most common type of melanoma reported in individuals with a dark complexion.[10] Similar to LMMs, this subtype is characterized by a protracted radial growth phase and is associated with mutations in *KIT*.

Uveal melanoma arises from the pigmented epithelium of the choroid. It is the most common primary intraocular malignancy seen in adults but is an uncommon tumor. Unlike cutaneous melanoma, the frequency and mortality rates of uveal melanoma have remained steady.[12] The risk of metastasis varies with the histologic type and size of the tumor and the location in the eye. The liver is the most frequent site of metastasis but uveal melanoma can spread to a variety of tissues.[10]

Clinical

Based on our understanding of the role of genetic alterations in the treatment and outcomes of patients with melanoma, four distinctive clinical subtypes have emerged based on UV exposure and anatomic site. The four subtypes are divided into (1) nonchronic sun damage (non-CSD): melanomas on the skin without chronic sun-induced damage; (2) chronic sun damage (CSD): melanomas on the skin with chronic sun-induced damage characterized by the presence of solar elastosis; (3) acral; and (4) mucosal.[8] The primary genetic differences of these subtypes are based on the activation of the MAPK and PI3K pathways. *BRAF* mutations predominantly occur in non-CSD (56%) and less commonly in the other groups. About 5% to 20% of all the subtypes contain *NRAS* mutations and these mutations occur independent of *BRAF*. Further studies showed *KIT* mutations are found in almost 40% of acral and mucosal subtypes, in almost one-third of CSD melanomas and not at all in non-CSD melanomas.[8] Guidelines recommend uveal and mucosal melanoma be treated differently than CSD and non-CSD melanoma because of their differences in presentation and outcomes.[8] This further emphasizes the need for continued refinement of tumor classifications in melanoma based on genetic and biological features, which will lead to more personalized treatment options and improved outcomes for patients.

PREVENTION AND DETECTION

① Skin cancer is a major health problem in the United States. In 2014, the US Surgeon General released a Call to Action to Prevent Skin Cancer that addressed the following goals to support skin cancer prevention: increase opportunities for sun protection in outdoor settings; provide individuals with the information they need to make informed, healthy choices about UV radiation exposure; promote policies to advance the national goal of preventing skin cancer; reduce harms from indoor tanning; and strengthen research, surveillance, monitoring, and evaluation related to skin cancer prevention.[13]

Both UVA and UVB exposure plays a major role in melanoma development and is the most preventable cause of melanoma. The incidence of melanoma has been associated with latitude and the intensity of solar exposure among susceptible populations. As such, the mainstay of melanoma prevention remains strategies to protect individuals from the harmful effects of the sun (see Table 162-2).

TABLE 162-2

Options for Sun Protection

	Sunscreens	
Behavioral	**Physical Blockers (Reflectants)**	**Chemical Absorbers**
Protective clothing and accessories Seek shade (avoid peak sun hours) Avoid tanning equipment	Zinc oxide Talc Titanium dioxide Red petrolatum	Ultraviolet B absorbers Salicylates Cinnamates Camphor derivatives Aminobenzoates Ultraviolet A absorbers Benzophenone-6 Dibenzoylmethanes

Strategies such as sun avoidance, especially during peak hours of sun intensity (10 AM–4 PM), seeking the shade when outdoors, and use of protective clothing are important education concepts for individuals who are in the sun for prolonged periods or who are at high risk for burning. In addition, the use of sunglasses, with both UVA and UVB protection, is important. Due to its correlation with the development of melanoma, the World Health Organization International Agency for Research on Cancer has declared UV light emitted from tanning beds a human carcinogen and the United States Food and Drug Administration (FDA) reclassified UV tanning devices to class II (moderate-to-high risk) devices.[14] As a result, 44 states have regulations in place to restrict minors' access to indoor tanning, including 23 that prohibit the use of indoor tanning for anyone younger than 18 years.

Sunscreens are another strategy to decrease UV exposure. A broad-spectrum sunscreen with both UVA and UVB protection and a SPF of 15 or higher used regularly as directed is recommended with other sun protective measures to prevent sunburn and reduce the risk of skin cancer. Of note, current regulations limit the SPF value on sunscreen labels to 50+ because of the lack of evidence to show that products with SPF values greater than 50 provide greater protection.[15] However, the FDA proposed several changes regarding labeling requirements and reducing the number of active ingredients to be generally recognized as safe and effective for over-the-counter sunscreen products. It is important to counsel patients about the appropriate use of sunscreen. Sunscreen should be applied 30 minutes before going into the sun and reapplied every 2 hours, after swimming or after perspiring heavily. About one ounce (30 mL) of sunscreen (a "palmful") should be used to cover the arms, legs, neck, and face of the average adult. Sun protection must be used regularly and not merely limited to times of recreation or anticipated "prolonged" exposure.

There are no consistent recommendations for the screening and early detection of melanoma. Early detection can play a large part in preventing a premalignant precursor from becoming melanoma or preventing a melanoma recurrence. About 50% of initial melanoma lesions are discovered by self-skin examination (SSE). Improved survival rates for melanoma have been attributed to the identification and treatment of disease at an early stage when the disease is limited and has not yet metastasized. High-risk patients with a strong family history should have additional clinical examinations, and in some cases, screening photography to document the size, shape, and location of moles. The entire cutaneous surface, including the scalp, should be examined. Both patients and clinicians need to be properly educated in the clinical features of the disease to ensure a more appropriate diagnosis.

In some cases, an individual may need the help of a partner or caregiver to perform a SSE. This is especially important for older adults as they are more likely to develop and die from melanoma. Barriers to successful SSEs in older adults, such as failing eyesight, lack of partners, and poor memory impact older adults in detecting new or changing lesions. These barriers, coupled with the higher incidence of melanoma in older adults, present challenges and opportunities for healthcare professionals to target education on this growing segment of our population.

Healthcare professionals who routinely work with the public have an opportunity to increase public awareness concerning the benefits and appropriate methods for SSE. Educational pamphlets describing SSE (see Table 162-3) for the public are widely available through the American Cancer Society, American Academy of Dermatology, and Skin Cancer Foundation. If a newly discovered pigmented lesion is identified on SSE, or if a preexisting pigmented lesion changes, the individual should be immediately evaluated by a clinician.

TABLE 162-3

Self-Examination of Suspicious Moles

1. Examine your body front and back in the mirror and then the right and left sides with the arms raised
2. Bend the elbows and look carefully at the forearms and upper arms and palms
3. Look at the backs of the legs and feet. Look specifically in the spaces between toes and at the soles of the feet
4. Examine the back of the neck and scalp with the help of a hand-held mirror; part the hair (or use a blow dryer) to lift the hair and give yourself a closer look
5. Check the back and buttocks with a handheld mirror

Data from the American Academy of Dermatology (www.aad.org).

Benign nevi often occur in sun-exposed areas and are typically 4 to 6 mm in diameter (about the size of a pencil eraser), raised or flat, uniform in color and round in shape. Dysplastic nevi, an intermediate between benign nevi and melanoma, tend to be larger than common nevi (>5 mm), appear as flat macules with asymmetry, have a fuzzy or ill-defined shape, and vary in color.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Melanoma

General

- Any lesion that changes in appearance over time

Local Signs and Symptoms

- The clinical features used to describe suspicious lesions are highlighted with the mnemonic "ABCDE"
    - Asymmetry: Melanoma lesions are often asymmetric
    - Border: Melanoma lesions have irregular borders
    - Color: Color is often variegated in a melanoma ranging from tan, blue-black, red, purple, or white
    - Diameter: Melanoma lesions are frequently greater than 6 mm
    - Enlargement or evolution: A sudden enlargement or change in the lesion is concerning for melanoma
- Other signs of melanoma include a lesion that swells, bleeds, or oozes

Systemic Signs and Symptoms

- Palpable lymph nodes
- Depending on the site of metastasis, shortness of breath, abdominal pain, bone pain, headache, and mental status changes

Laboratory Tests

- In addition to a comprehensive metabolic panel, LDH should be evaluated

Other Diagnostic Tests

- Biopsy and pathology review for staging with molecular testing for *BRAF, NRAS* and *KIT*
- When applicable, SLNB
- Systemic staging should include chest, abdomen, and pelvic CT scan or CT/PET bone scan, and brain MRI

CT, computed tomography; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; PET, positron emission tomography; SLNB, sentinel lymph node biopsy.

The initial clinical presentation of melanoma is often a cutaneous pigmented skin lesion that changes over time. Any changes in the skin surrounding a nevus, including redness or swelling, are important clinical signs. Uncommonly, the lesion may become itchy or tender and painful. Friability of the lesion, resulting in bleeding or oozing, is a danger sign. Perhaps the most important warning sign of danger is the evolution of any characteristic of a lesion. A biopsy of the lesion is critical to establish the diagnosis of melanoma. Subsequent pathologic interpretation of the biopsy will provide information on prognosis and treatment options. An excisional biopsy, with a 1- to 3-mm margin of normal appearing skin, is recommended for a suspicious lesion and should include a portion of underlying subcutaneous fat for microstaging. For larger lesions, an incisional or punch biopsy can be performed and should include a core of full-thickness skin and subcutaneous tissue. When excisional biopsies are not appropriate, as with the face or palmar surface of the hands, a full-thickness incisional or punch biopsy is preferred. A shave biopsy is rarely appropriate because it can underestimate the thickness of the lesion, and may not fully remove it. A broad shave biopsy could be considered for melanoma in site or LMM. Evaluation of any individual with a suspected melanoma includes a complete history and total-body skin examination. The focus of the patient history is to identify potential risk factors including family history of melanoma, personal history of skin cancer or nevus excisions, immunosuppression or an immunosuppressive condition, sun exposure, tanning bed use, and phenotype. A total dermatologic examination is necessary to determine melanoma risk factors (eg, mole pattern, mole type, or freckling) and for staging. Since melanoma commonly spreads to the lymph nodes, individuals suspicious for advanced disease should be examined for lymphadenopathy. Lactate dehydrogenase (LDH) should be measured because elevated serum levels are an independent predictor of decreased survival.[8,16] In addition, any other signs or symptoms suggestive of metastatic disease should be completely evaluated.

STAGING AND PROGNOSTIC FACTORS

The size of a primary melanoma lesion is associated with the likelihood of metastasis. The Breslow tumor thickness of the lesion is commonly used as a prognostic factor to predict outcomes.[6] Tumor thickness is quantified to the nearest 0.1 mm with an ocular micrometer, measuring from the top of the granular layer of the overlying epidermis to the deepest contiguous invasive melanoma cell. The correlation between tumor thickness and the risk of tumor metastasis is strong but does not include aspects such as tumor satellites, defined rather arbitrarily, as skin involvement within 2 cm of the primary lesion, and vascular invasion. Patients with satellitosis have a worse prognosis than patients with thick primary lesions (tumor thickness > 4 mm), and the prognosis is more similar to that of patients with nodal metastasis. The American Joint Committee on Cancer (AJCC) developed an early-staging system for melanoma that divides patients with localized melanoma into four stages according to the microstaging criteria of Breslow. Additionally, ulceration of the melanoma, satellite lesions of the primary tumor, and location of distant metastases must be considered for accurate staging. As a result, the revised AJCC staging system for cutaneous melanoma was implemented in 2018.[16] Carefully examine older clinical trials to determine which staging system was used to determine patient inclusion and exclusion criteria, as results may differ based on these patient criteria. Clinical staging includes microstaging the primary melanoma with clinical, laboratory, and radiologic evaluation. It is used after complete excision of the primary melanoma and clinical assessment to determine regional and distant metastasis. Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional nodes after partial or complete lymphadenectomy. Patients with limited disease (in situ, stage 0 or stage 1A) do not require pathologic evaluation of lymph nodes (see Tables 162-4 and 162-5).[8]

TABLE 162-4

Melanoma Tumor (T), Node (N), Metastasis (M) Classification

T Classification	Thickness	Ulcerative Status
T_X	Primary tumor cannot be addressed (eg, shave biopsy)	
T_0	No evidence of primary tumor	
T_{is}	Melanoma in situ	
T_1	≤1 mm	Unknown or unspecified
	0.8-1 mm	With or without ulceration
	<0.8 mm	A: Without ulceration B: With ulceration
T_2	>1-2 mm	Unknown or unspecified A: Without ulceration B: With ulceration
T_3	>2-4 mm	Unknown or unspecified A: Without ulceration B: With ulceration

T_4	>4 mm	Unknown or unspecified A: Without ulceration B: With ulceration
N Classification	**No. of Tumor Involved Nodes**	**Presence of In-Transit, Satellite, and/or Microsatellite Metastases**
N_X	Regional lymph nodes cannot be assessed	No
N_0	No regional lymph nodes	No
N_1	1 node	
N_{1a}	1 clinically occult node[a]	No
N_{1b}	1 clinically detected node	No
N_{1c}	No regional lymph node disease	Yes
N_2	2-3 nodes	
N_{2a}	2-3 clinically occult nodes	No
N_{2b}	2-3, with 1 clinically detected node	No
N_{2c}	1 clinically occult or detected node	Yes
N_3	≥4 nodes	
N_{3a}	≥4 clinically occult nodes	No
N_{3b}	≥4, with 1 clinically detected, or presence of any matted nodes	No
N_{3c}	≥2 clinically occult or detected and/or any matted nodes	Yes
M Classification	**Site**	**Serum Lactate Dehydrogenase**
M_0	No detectable distant metastasis	
M_{1a}	Distant skin, soft tissue, and/or nonregional lymph nodes	Not elevated Elevated: $M_{1a(1)}$
M_{1b}	Lung metastases	Not elevated Elevated: $M_{1b(1)}$
M_{1c}	Any distant metastasis visceral metastases	Not elevated Elevated: $M_{1c(1)}$

M_{1d}	Distant metastases to the CNS	Not elevated Elevated: $M_{1d(1)}$

M, metastasis; N, node; T, tumor.

[a] Clinically occult node detected by sentinel lymph node biopsy.

Data from Reference 17.

As with other solid tumors, regional lymph node involvement is a powerful predictor of tumor burden and patient outcome. Sentinel lymph node biopsy (SLNB) is a minimally invasive procedure that determines if a patient is a candidate for a complete lymph node dissection. The rationale for lymphatic mapping and subsequent SLNB is based on the observation that skin regions have patterns of lymphatic drainage to specific lymph nodes in the regional lymphatic basin. The sentinel lymph node is the first node in the lymphatic basin into which the primary melanoma drains. Unlike other solid tumors, melanoma progresses in an orderly nodal distribution. SLNB allows for the detection of micrometastases with a more thorough examination of a single sentinel node than is possible when examining multiple lymph nodes with a lymph node dissection. SLNB is associated with low false-negative rates and low complication rates.[18] SLNB may be most useful for melanomas located in ambiguous drainage sites such as the head and neck. Detection of clinically undetectable disease in a lymph node basin not directly adjacent to the primary lesion may allow for upstaging of patients who initially are believed to have node-negative disease. The American Society of Clinical Oncology and Society of Surgical Oncology joint clinical practice guidelines recommend SLNB for patients with any intermediate-thickness melanoma and may be considered for a thinner melanoma.[18]

Tumor thickness, ulceration, and mitotic rate, in addition to age and gender, are the primary indicators of the natural history of the disease and correlate with prognosis. Mitotic rate, defined as the number of mitosis per square millimeter, is an important prognostic factor for developing metastatic disease. Increasing mitotic rate, characterized as greater than ≥1 mitosis/mm^2, represents a more aggressive lesion and is associated with a poorer survival rate. Other factors such as tumor growth pattern, vertical growth phase, histological subtype, density of tumor-infiltrating lymphocytes (TILs) in the tumor tissue, elevated LDH level, satellite lesions, and angiolymphatic invasion may be associated with survival.[19] The location of the primary tumor on the skin is also important as tumors of the extremities have increased survival compared with those with axial, neck, head, and trunk tumors. In addition, several additional prognostic factors have been identified in patients with advanced disease. The number of metastatic sites, involvement of the central nervous system, gastrointestinal tract, liver, pleura, or lung, Eastern Cooperative Oncology Group (ECOG) performance status of 1 or greater, male sex, and prior immunotherapy have all been associated with poor prognosis.[8]

TREATMENT

Desired Outcomes

Treatment of cutaneous melanoma depends on the stage of disease. Localized disease is managed, and often cured, with surgical ablation. Regional disease is treated with surgical resection of the primary lesion and, depending on the risk of recurrence, adjuvant therapy to eradicate any residual disease and cure the patient. The role of ipilimumab as adjuvant therapy after surgical resection is limited with combination BRAF and MEK inhibitors and PD-1 inhibitors now favored in this setting based on recent FDA approvals. Historically, metastatic melanoma has been a difficult disease to treat. The goals of treatment for metastatic disease are to slow tumor progression, prolong survival, relieve acute symptoms, and improve quality of life. After decades of poor treatment options, several effective treatment options are now available, including targeted agents (BRAF and MEK inhibitors) and immunotherapy (CTLA-4 and PD-1 inhibitors) approved to treat metastatic melanoma. Targeted agents offer rapid and high-response rates with prolonged time-to-disease progression, while immunotherapy can induce durable responses. These new treatment options have increased survival expectations to an all-time high in the history of melanoma treatment. As a result of the differences in the underlying pathophysiology and treatment of uveal melanoma, the NCCN developed disease-specific guidelines.[20]

Surgery

Patients who present with a suspicious pigmented lesion should undergo a full-thickness excisional biopsy, if possible. A full-thickness incisional or punch biopsy is preferred in cases where an excisional biopsy is not possible, to provide microstaging and ultimately determine therapy.

② Localized cutaneous melanoma can often be cured with surgical excision. The cure rates for melanomas smaller than 1 mm are as high as 98%.[21] The extent of the excision margin determines the risk of local recurrence and ultimately survival. For melanoma in situ, excision of the visible lesion or biopsy site with a 0.5- to 1 cm border of clinically normal skin and a layer of subcutaneous tissue along with confirmation of histologically negative peripheral margins is recommended. The recommended clinical margin for invasive melanoma depends on tumor thickness. Excision with a 1-cm margin of clinically normal skin and underlying subcutaneous tissue is recommended for invasive melanomas 1 mm thick or smaller. Current guidelines recommend a 1 to 2 cm margin for melanoma with a tumor thickness of 1.01 to 2 mm.[8] Lesions that are 2 to 4 mm thick should be excised with a 2 cm margin and primary tumors more than 4 mm thick require at least a 2 cm margin. Surgical management of lentigo maligna melanoma is problematic as subclinical extension of atypical junctional melanocytic hyperplasia may extend beyond the visible margins. Complete excision of these lesions is important.

When isolated regional lymph nodes in the absence of distant disease are detected via physical examination, a therapeutic lymphadenectomy is recommended. Neoadjuvant therapy should also be considered in patients at high risk of perioperative morbidity or if gross complete resection of nodal disease may not be achieved. The extent of the therapeutic lymph node dissection is often modified according to the anatomic area of the lymphadenopathy. Selective regional lymphadenectomy performed after scintigraphic and dye lymphographic identification of the affected draining sentinel lymph node(s) is the standard of care for melanomas more than 1 mm thick. If the lesion is less than 0.8 mm in thickness with ulceration, 0.8 to 1 mm in thickness with or without ulceration, or <0.8 mm with other adverse features (very high mitotic index >2/mm^2 or lymphovascular invasion), lymphatic mapping with SLNB should be discussed and considered. If the sentinel node is found to have micrometastatic melanoma, regional dissection of the involved nodal basin is performed. The likelihood of detecting metastatic disease in the sentinel lymph node is <5% in thin melanomas that are less than 0.8 mm, but increases to more than 30% in tumors 4 mm thick.[22] The Multicenter Selective Lymphadenectomy Trial (MSLT-1) investigated the use of SLNB and immediate complete lymph node dissection (CLND) compared to nodal observation in patients with melanoma undergoing a wide local excision. Results showed a significant improvement in disease-free survival but not melanoma-specific survival, supporting the staging value of SLNB.[23] The Multicenter Selective Lymphadenectomy Trial II (MSLT-II) then randomized sentinel lymph node-positive patients to either CLND or nodal observation. No difference in melanoma-specific survival was observed despite an increased rate of regional disease control.[24] As a result, the value of CLND in routine practice remains unclear, with nodal basin ultrasound surveillance preferred for patients without clinically positive nodes.[8] However, SLNB results are important for accurate staging and aid in the decision to offer adjuvant treatment.[22]

One of the most important aspects of surgical management for cutaneous melanoma is patient follow-up. Postsurgical follow-up of patients who have had a melanoma excised is essential to monitor for undetected metastatic disease and the development of a second primary cutaneous melanoma or nonmelanoma malignancy. Scheduled screening, in addition to routine surgical follow-up, is required for any patient with a melanoma; the recommended frequency and duration depend on the stage of melanoma. The optimal duration of follow-up remains controversial. Most patients who develop recurrent disease do so within the first 5 years after treatment but late recurrences (more than 10 years after surgery) have been observed. The increased lifetime risk of developing a second primary melanoma supports lifetime dermatologic surveillance for all patients.[8]

A patient with stage III melanoma typically has lymph node involvement but intralymphatic metastases, including satellite metastases and in-transit metastases, may also occur. Satellite metastases are either clinically (visible) or pathologically (microscopic) detectable and occur within 2 cm of the primary site. In-transit metastases are defined as regional metastases that occur more than 2 cm from the original lesion and are more common in individuals with thick, ulcerated lesions.[8] Surgery may be used to manage in-transit lesions with the goal of complete resection with clear margins. Unfortunately, surgery is not always feasible and subsequent recurrence in the same extremity often occurs after initial resection of an in-transit metastasis.

The role of surgery beyond that of cure is less clear, although surgery may offer palliation for patients with isolated metastasis.[22] Brain metastases occur in up to 50% of patients with metastatic melanoma. Surgical resection, with or without radiation, has been used in select individuals. High control rates of brain metastasis have been achieved with focal radiation therapy such as linear accelerator–based stereotactic radiosurgery or gamma-knife technologies.[8] Surgical resection or bypass may also offer significant symptom relief to patients with a bowel obstruction due to metastasis. Despite the lack of controlled clinical trials, the impact of palliative surgery should be evaluated in the context of a patient's comfort and quality of life. Surgery may improve quality of life, result in long-term disease control, and extend survival in select patients with metastatic disease.[22]

Adjuvant Therapy

③ The risk of relapse and death after resection of a local or regional cutaneous melanoma is the primary determinant for the use of adjuvant therapy. Adjuvant trials have focused on patients at intermediate or high risk for recurrence.

Historically, melanoma has shown resistance to traditional treatment modalities such as radiation and chemotherapy. However, melanoma is considered one of the most immunogenic solid tumors and lymphocyte infiltration in the tumor suggests that immunomodulation may impact the biology of the disease. Early work with nonspecific immunomodulators, such as levamisole and Bacillus Calmette-Guérin (BCG), resulted in tumor regression but many of these responses were limited and short-lived. The use of adjuvant immunotherapy to treat these patients has been investigated to prevent distant recurrence and improve long-term survival.

CTLA-4 Inhibitor

It is well known that T cells play a crucial role in cell-mediated immunity. They are activated when the T-cell receptor (TCR) binds to its antigen in conjunction with the binding of CD28 on the T cell to the costimulatory molecule B7 on antigen-presenting cells (APCs). To prevent over activation of T cells, immune checkpoints such as CTLA-4 function as inhibitory receptors for the costimulatory molecule B7. Crosslinking of CTLA-4 by B7 inhibits T-cell activation, transcription, translation, and transduction. CTLA-4 blockade overcomes this inhibition and results in the activation and proliferation of T cells.[11] Ipilimumab, a monoclonal antibody against CTLA-4, has efficacy in both the adjuvant and metastatic setting in the treatment of melanoma. The EORTC 18071 trial evaluated 475 patients treated with high-dose ipilimumab as compared to placebo in the adjuvant setting. Median recurrence-free survival was longer in patients treated with high-dose ipilimumab as compared with placebo (26.1 vs 17.1 months). Long-term data demonstrated significantly higher 5-year recurrence-free and overall survival with adjuvant ipilimumab as compared to placebo.[25]

However, these results did not come without toxicity. CTLA-4 inhibitors produce immune-related adverse events (irAEs) that are distinct and different from adverse drug reactions associated with conventional cancer treatments (see Table 162-6). irAEs are the result of the activation of self-reactive T cells. The incidence of irAEs with the high-dose ipilimumab in EORTC 18071 was 90% and up to 55% of patients experienced grade 3 or 4 irAEs.[25] The most common serious irAEs observed in the EORTC 18071 adjuvant trial were autoimmune colitis and autoimmune hepatitis. Autoimmune endocrinopathies occurred at a higher frequency than in the metastatic disease trials. irAEs led to treatment discontinuation in 52% of patients treated with ipilimumab. Of concern, five deaths were attributed to adverse drug reactions.[25]

TABLE 162-6

Management of Immune-Related Adverse Effects (irAEs)

Organ Toxicity	Signs/Symptoms	Management	Comments
Skin and Mucosa	Pruritus, rash, desquamation, mucositis	Grade 1 Topical corticosteroids (betamethasone 0.1%) Urea-based creams Oral antipruritic as needed (diphenhydramine or hydroxyzine) Grade 2 Moderate-high potency topical corticosteroids If unresponsive to topical, consider prednisone 0.5 mg/kg/day Oral antipruritic as needed (diphenhydramine or hydroxyzine) Grade 3 or 4 Hold therapy High-potency topical corticosteroids to affected areas Prednisone 0.5-1 mg/kg/day or equivalent (increase up to 2 mg/kg/day if no improvement) Consider inpatient care	Rare cases of toxic epidermal necrosis and Stevens–Johnson syndrome have been reported. Permanent discontinuation of immunotherapy is warranted in these cases.

Gastrointestinal	Diarrhea, hematochezia, abdominal cramping, nausea, and vomiting	Grade 1 Consider holding treatment Oral hydration/electrolyte repletion Close monitoring Loperamide or diphenoxylate hydrochloride Grade 2 Hold immunotherapy Prednisone/methylprednisolone 1-2 mg/kg/day No response in 2-3 days, consider adding infliximab or vedolizumab Grade 3 or 4 Consider inpatient care Methylprednisolone 1-2 mg/kg/day No response in 1-2 days, add infliximab or vedolizumab	Infliximab 5 mg/kg IV may be given if symptoms do not improve with 48-72 hours of high-dose steroids. Bowel perforation and obstruction may occur in cases of severe colitis.
Hepatic	Transaminitis, jaundice, sclera icterus	Grade 1 Consider holding therapy Increase lab monitoring Grade 2 Hold therapy Monitor liver function tests every 3-5 days Consider prednisone 0.5-1 mg/kg/day Grade 3 Hold treatment Prednisone 1-2 mg/kg/day or equivalent No response in 1-2 days, consider adding mycophenolate Grade 4 Permanently discontinue treatment Prednisone/methylprednisolone 1-2 mg/kg/day or equivalent Inpatient care Monitor liver enzymes daily	Mycophenolate mofetil 500 mg IV/PO every 12 hours can be used in patients who do not respond to steroids within 48 hours Avoid infliximab in hepatitis
Neurologic	Muscle weakness, motor neuropathies, sensory neuropathies	Grade 1-2 Consider holding treatment Monitor Grade 3 or 4	Rare case reports of Guillain–Barre' syndrome and myasthenia gravis have been reported with ipilimumab

		Inpatient care Permanently discontinue treatment Methylprednisolone 1-2 mg/kg/day Prednisone If severe or progressing symptoms, consider pulse steroids methylprednisolone 1 g IV daily × 3-5 days plus IVIG or plasmapheresis	
Endocrine	Headache, weakness, visual changes, behavioral changes, electrolyte imbalances	Grade 1 or 2 Appropriate hormone replacement therapy Endocrine consultation Grade 3 or 4 Hold therapy until acute symptoms resolve Carefully consider high-dose steroids for acute severe symptoms	Potential endocrinopathies include Addison's disease, pan-hypopituitarism, adrenal crisis, and hypophysitis These effects may be permanent
Ocular	Photophobia, eye dryness, blurred vision	Grade 1 or 2 Consider holding treatment Prednisolone acetate 1% topical Grade 3 or 4 Hold treatment Ophthalmic and systemic prednisone/methylprednisolone	Rare cases of episcleritis and uveitis have been reported
Pulmonary	Dyspnea, new or worsened cough, chest pain, hemoptysis	Grade 1 Consider holding treatment Consider chest CT with contrast Grade 2 Hold treatment Consider infectious workup Prednisone 1-2 mg/kg/day or equivalent If no improvement after 2-3 days, treat as Grade 3 Grade 3 or 4 Permanently discontinue treatment Methylprednisolone 1-2 mg/kg IV then 1-2 mg/kg/day of oral prednisone or equivalent If no improvement after 2 days,	Pneumonitis is more common with pembrolizumab and nivolumab than ipilimumab

		consider adding infliximab, IVIG, or mycophenolate	

Data from Reference 26.

The incidence of irAEs with ipilimumab are dose-related and tend to follow a pattern: skin-related toxicities typically occur after the first dose; colitis tends to occur after the second dose; and hepatitis and endocrinopathies often occur after the third or fourth dose.[27] However, irAEs can occur at any time during treatment and even after the treatment is discontinued. Their development cannot be predicted because they result from the individual's immune system and not the treatment itself. Most irAEs are reversible with treatment and resolve after 6 to 8 weeks; the exception being endocrinopathies which may require lifelong hormonal treatment. Close monitoring and early intervention are necessary for effective management of irAEs while on therapy.[8] It is recommended that patients obtain a comprehensive metabolic panel (with liver function tests), complete blood count, and thyroid function tests at baseline, throughout treatment and for up to 6 months after treatment.[26,27]

Ipilimumab therapy should be held and high-dose systemic corticosteroids initiated for grade 2 irAEs that do not improve from withholding therapy or for any grade 3 or 4 irAE. Consideration may be given to restart ipilimumab after an irAE improves to grade 0 or 1 and systemic corticosteroid dose is less than or equal to prednisone 10 mg per day. In early studies, corticosteroids were discouraged due to the theoretical risk of blunting the desired immune response. However, the efficacy of ipilimumab is not compromised when corticosteroids are given for toxicity management.[26] For patients who develop steroid-refractory irAEs, defined as no response to high-dose steroids within 48 to 72 hours of initiation, other immunosuppressive agents have been used in addition to corticosteroids. For example, infliximab and mycophenolate have been used as secondary immunosuppressants for patients who develop steroid-refractory colitis and hepatitis, respectively. Due to case reports of hepatotoxicity with infliximab, this agent should be avoided in patients with autoimmune hepatitis. Published guidelines for the treatment of irAEs are available.[26] In cases of severe or life-threatening irAEs, permanent discontinuation of ipilimumab therapy is recommended. In clinical studies reported to date, patients who experienced grade 3 or 4 autoimmune toxicities were also the most likely to exhibit tumor regression and increased time to relapse in the metastatic setting.[26]

PD-1 Inhibitors

Physiologically, the binding of PD-1 to its ligand (PD-L1 or PD-L2) results in an inhibitory signal to suppress T-cell activation, therefore preventing autoimmunity and recognition of self. However, melanoma cells can overexpress PD-L1, leading to T-cell exhaustion and the inability to mount an immune response against a tumor. Monoclonal antibodies directed against PD-1 block the binding of PD-L1, thus allowing T cells to remain stimulated.[7] PD-1 inhibitors have exhibited improved efficacy and reduced toxicity compared to ipilimumab.

Pembrolizumab and nivolumab are PD-1 inhibitors initially approved for the treatment of metastatic melanoma that have been evaluated in the adjuvant setting. Checkmate-238 was the first in a series of published adjuvant studies that changed the treatment landscape of early-stage melanoma. A total of 906 patients with high-risk stage III or stage IV melanoma who underwent complete resection were randomized to receive either ipilimumab 10 mg/kg IV every 3 weeks for four doses then every 12 weeks or nivolumab 3 mg/kg IV every 2 weeks for up to 1 year. Results showed 1-year recurrence-free survival of 70.5% with nivolumab as compared to 60.8% with ipilimumab.[28] The risk of grade 3 to 4 toxicities was significantly lower in the patients receiving nivolumab (14.4%) versus ipilimumab (45.9%). Treatment discontinuation due to an adverse drug reaction occurred in 9.7% of patients treated with nivolumab versus 42.6% of patients treated with ipilimumab.[28] With longer follow-up, nivolumab has demonstrated a sustained recurrence-free survival benefit over ipilimumab. However, fewer deaths than anticipated occurred and 4-year overall survival was similar in both groups.[29] Based on these results, nivolumab is an efficacious adjuvant treatment with less toxicity than ipilimumab.

A similar study of adjuvant pembrolizumab, Keynote-054, was conducted in patients with stage III melanoma undergoing complete resection. Patients were randomized to receive pembrolizumab 200 mg IV every 3 weeks or placebo for up to 1 year. The 1-year recurrence-free survival rate was 75.4% with pembrolizumab compared to 61.0% with placebo. Grade 3 to 4 adverse drug reactions were reported in 14.7% of patients who received pembrolizumab.[30] Based on these two studies, PD-1 inhibitors are now considered the standard of care for the adjuvant treatment of melanoma in patients with stage III disease who have undergone complete resection.[8]

With significant benefit seen in stage III melanoma, adjuvant treatment with PD-1 inhibitors has been studied in patients with high-risk stage II disease.

KEYNOTE-716 was a multicenter, randomized, double-blind, placebo-controlled trial that randomized patients with fully resected stage IIB or IIC melanoma to receive either pembrolizumab 200 mg every 3 weeks or placebo for up to 1 year. At a median follow-up of 14.4 months, this study showed a significant improvement in recurrence-free survival, with a 35% reduction in risk in those who received pembrolizumab compared to placebo.[31] Although further follow-up is needed to evaluate if there is an overall survival benefit, the FDA approved pembrolizumab for the adjuvant treatment of patients with stage IIB or IIC melanoma following complete resection based on this data. This approval supports the introduction of immunotherapy, specifically PD-1 inhibitors, in the adjuvant setting due to their ability to reduce the risk of melanoma recurrence and their favorable toxicity profile.

Targeted Therapy

Mutations in BRAF, found in up to 50% of melanomas, lead to the constitutive activation of the MAPK pathway and uncontrolled cell growth/differentiation.[7] BRAF-targeted therapies have shown an improvement in survival in patients with metastatic melanoma. However, resistance eventually develops, potentially caused by mutations in MEK. The use of MEK inhibitors in combination with BRAF inhibitors delays the development of acquired resistance and increases efficacy in the metastatic setting.

For patients with early-stage melanoma and molecular mutations identified in BRAF, the combination of BRAF and MEK inhibitors has been studied in the adjuvant setting. The COMBI-AD trial investigated the use of adjuvant dabrafenib and trametinib in patients with completely resected, stage III melanoma, and the presence of a *BRAF* V600E or V600K mutation. Patients were randomized to receive dabrafenib 150 mg twice daily plus trametinib 2 mg daily or placebo for up to 1 year. The 3-year relapse-free survival rate was 58% in the dabrafenib/trametinib group and 39% in the placebo group, with a 53% lower risk of relapse at 2.8 years.[32] Overall survival was also increased in the combination arm but this did not reach statistical significance in the first interim analysis. No new or unexpected adverse drug reactions were observed in the adjuvant setting. Relapse-free survival at 5 years was 52% in patients treated with dabrafenib and trametinib versus 36% with placebo and no long-term adverse drug reactions were seen.[33] The major toxicities of BRAF and MEK inhibitor therapy will be discussed in the Treatment of Metastatic Melanoma section. Based on this data, the combination of dabrafenib and trametinib received FDA approval for adjuvant treatment in patients with stage III melanoma and the presence of a *BRAF* V600E or V600K mutation following complete resection.

Summary of Adjuvant Therapy

High-dose ipilimumab is a treatment option for patients with high-risk disease, but it has fallen out of favor because of its toxicities and has been removed from the list of recommended adjuvant treatment options in the NCCN guidelines. The treatment of choice in this setting is PD-1 inhibitors (nivolumab or pembrolizumab) or dabrafenib and trametinib for patients with BRAF V600-activating mutation due to improved efficacy and reduced toxicity.[8]

Treatment of Metastatic Melanoma

Chemotherapy and Biochemotherapy

④ Although many chemotherapy drugs show in vitro activity against melanoma, only a few have consistently shown a response rate greater than 10% in individuals with metastatic melanoma. Dacarbazine and temozolomide, the oral prodrug of the active metabolite of dacarbazine, are alkylating agents that have been studied in the treatment of metastatic melanoma. Dacarbazine is the only FDA-approved chemotherapeutic agent for treatment in this setting and once was considered the standard of care. Reported response rates with these two cytotoxic drugs are 10% to 25%, with an average duration of response of 5 to 7 months.[8] Common adverse drug reactions include myelosuppression and severe nausea and vomiting. Carboplatin in combination with paclitaxel demonstrated activity in the second-line setting.[34] Response rates of 15% to 17% were seen in trials with single-agent paclitaxel.[8] A phase III trial comparing albumin-bound paclitaxel with dacarbazine in chemotherapy-naïve melanoma patients reported an increase in progression-free survival and a trend in overall survival in patients receiving albumin-bound paclitaxel. Neuropathy and neutropenia were more common in the albumin-bound paclitaxel arm.[35] The NCCN guidelines state that these chemotherapy agents should not be routinely used because of their lack of overall survival benefit and toxicity and should only be considered for patients who are not candidates for immunotherapy or targeted therapy.[8]

To improve the low response rates with chemotherapy, the strategy of combining chemotherapy (dacarbazine, platinum agents, or vinca alkaloids) and cytokines (aldesleukin or interferon), often termed biochemotherapy, has been evaluated for the management of metastatic melanoma as well as the adjuvant setting. The primary rationale for this combination is to increase overall activity and response rates based on preclinical work suggesting potential synergistic interactions between cytokines and some chemotherapy agents. Results of clinical studies with biochemotherapy have not demonstrated a clear survival advantage and toxicities are additive and can be severe. The NCCN guidelines do not recommend biochemotherapy in the adjuvant or metastatic setting.[8]

Immunotherapy

Significant attention has been given to immunotherapy as a treatment option in metastatic melanoma due to its general resistance to traditional treatment modalities. Over the past decade, advances in immunotherapy for the treatment of melanoma have improved survival in patients with metastatic disease.

Interleukin-2

Interleukin-2 is a glycoprotein produced by activated lymphocytes. IL-2 was first identified as a T-cell growth factor, but IL-2 is also a growth factor for various cells, including lymphocytes and natural killer (NK) cells. The precise mechanism of cytotoxicity of IL-2 is unknown. In vitro and in vivo, IL-2 stimulates the production and release of many secondary monocyte-derived and T-cell–derived cytokines, including IL-4, IL-5, IL-6, IL-8, tumor necrosis factor (TNF)-α, granulocyte-macrophage colony-stimulating factor, and IFN-γ, which may have direct or indirect antitumor activity. In addition, IL-2 stimulates the cytotoxic activities of NK cells, monocytes, lymphokine-activated killer (LAK) cells, and cytotoxic T lymphocytes (CTLs). IL-2 also activates endothelial cells, which results in increased expression of adhesion molecules.[36]

High-dose IL-2, as known as aldesleukin, was evaluated in a series of trials with objective response rates around 16%. Of significance, 6% of those patients exhibited durable complete responses (median response, 70 months).[36] Responses were seen in various metastatic sites such as the lung, liver, bone, lymph nodes, and subcutaneous tissue. The FDA-approved high-dose aldesleukin regimen for the treatment of metastatic melanoma is 600,000 IU/kg/dose every 8 hours for a maximum of 14 doses in a 5-day period given for two cycles, with a 10- to 14-day rest period between cycles. At these doses, cytokine-induced capillary leak syndrome is a common problem and often is accompanied by significant hypotension, visceral edema, dyspnea, tachycardia, and arrhythmias. Increased permeability of capillary walls allows for a fluid shift from the intravascular space into tissues. Hypotension may occur as the patient becomes intravascularly dehydrated, resulting in reflex tachycardia and arrhythmias. In addition, the decrease in blood volume may result in decreased renal blood flow, manifesting as increases in blood urea nitrogen, serum creatinine, edema, and weight gain, and a decrease in urine output (input greater than output). Visceral edema may result in pulmonary congestion, pleural effusions, and edema. The management of patients receiving high-dose aldesleukin requires extensive supportive care medications, careful monitoring, and staff trained in aspects of critical care such as hypotension management. Constitutional symptoms are a frequent complication of aldesleukin therapy and become more intense as therapy progresses. Additional adverse drug reactions of aldesleukin include pruritus, eosinophilia, bone marrow suppression, increased liver function tests, neurologic disturbances, diarrhea, and nausea.[8]

Careful patient selection for aldesleukin therapy is important. Pretreatment factors such as performance status, site of metastasis, and LDH may predict who will respond. Based on reports of long-term responses (>10 years) experienced by some patients, the benefit certainly exceeds the risk for those individuals. Unfortunately, it is difficult to determine which individuals will respond to aldesleukin therapy because no biologic or immunologic biomarkers have been found to correlate with response. The decision to treat an individual with high-dose aldesleukin should be based on an analysis of an individual patient's risk versus potential benefit. With newer agents now available on the market, and its complexity of administration, the role of aldesleukin has diminished.[8]

CTLA-4 Inhibitors

⑤ CTLA-4 was the first immune checkpoint identified as a target for immunotherapy and ipilimumab was the first drug in this class to demonstrate efficacy in metastatic melanoma. Results from phase I and II trials with ipilimumab demonstrate up to 20% response rates in advanced disease.[8] In a phase III trial of 676 HLA-A*0201-positive patients with refractory metastatic melanoma, ipilimumab (3 mg/kg) plus a glycoprotein 100 (gp100) peptide vaccine was compared with ipilimumab (3 mg/kg) alone or gp100 alone.[8] The median overall survival time was significantly longer in patients treated with ipilimumab, alone or combined with gp100, as compared with patients treated with gp100 alone. Another phase III trial compared a higher dose of ipilimumab (10 mg/kg) plus dacarbazine with dacarbazine alone in patients previously untreated for metastatic melanoma. Ipilimumab plus dacarbazine demonstrated significantly longer median overall survival and higher survival rates at 1 year (47.3% vs 36.3%), 2 years (28.5% vs 17.9%), and 3 years (20.8% vs 12.2%) than dacarbazine alone.[8] Based on these results, ipilimumab, dosed at 3 mg/kg IV every 3 weeks for four doses became the first FDA-approved drug for the treatment of unresectable or metastatic melanoma with a survival benefit. With longer follow-up, the survival benefit was maintained in patients who had an initial response to ipilimumab. Five-year follow-up data demonstrate survival rates of 13% to 23% with survival durations of 13 to 16 months.[37] It is also important to note that the 3-year survival mark is noteworthy for patients treated with ipilimumab. Up to 85% of the patients who were alive at 3 years were alive at 4 years, suggesting that the 3-year survival mark may be a useful surrogate endpoint.[38] After a period of time, it is felt that the balance between immune response and tumor growth can shift leading to disease relapse after an extended duration of response. Retreatment can be an option for patients who had an initial clinical benefit and has been shown to re-induce a response; no additional toxicities have been observed with re-induction.[34]

One of the greatest lessons learned from early clinical trials with ipilimumab was the difference in the kinetics of response seen with immunotherapies and how to evaluate response to treatment. Patients have no regression of disease for many weeks after treatment initiation. Even more alarming was around 10% of patients initially experienced a significant increase in tumor burden which suggested disease progression. This pseudoprogression was then followed by a delayed response to the drug after about 12 weeks of therapy; some patients continued to have a steady reduction in tumor burden over time which eventually produced a durable clinical benefit. It is hypothesized that the delayed response is related to the time needed to stimulate the immune system.[37] Due to this phenomenon, the Response Evaluation Criteria in Solid Tumors (RECIST) has developed immune-related response criteria (irRECIST) to evaluate response to immunotherapies.[39]

⑥ The greatest challenge with the use of ipilimumab is the management of irAEs. Patients must be thoroughly educated on signs and symptoms of irAEs and when to seek medical attention. Clinicians should be familiar with the different types, timing, and appropriate management of irAEs (see Table 162-6). As previously discussed, management of irAEs should follow established treatment guidelines.[26]

PD-1 Inhibitors

⑤ As the next generation of immune checkpoint inhibitors, these agents have demonstrated response rates of up to 40% in metastatic melanoma with long-term clinical benefit seen in early phase I trials.[40] It became clear that PD-1 inhibitors have a more favorable safety profile with significantly fewer irAEs compared to ipilimumab. Additionally, clinical benefit was seen in patients who had previously been treated with ipilimumab. The KEYNOTE-001 trial evaluated the efficacy of pembrolizumab in patients who were previously treated with ipilimumab. The trial reported an overall response rate of 26%, progression-free survival of 45% at 24 weeks, and 1-year overall survival of 58%.[41] Treatment was well tolerated with grade 3 or 4 adverse events occurring in 12% of patients. In the CheckMate 037 randomized controlled trial of patients previously treated with ipilimumab, nivolumab produced higher response rates (32% vs 11%) with fewer irAEs when compared to chemotherapy.[42] An important observation from these studies is the lack of cross-resistance between ipilimumab and PD-1 inhibitors. As with ipilimumab, if patients are able to achieve a response to these agents, that response can be maintained for an extended duration. Both pembrolizumab 2 mg/kg IV every 3 weeks and nivolumab 3 mg/kg IV every 2 weeks were approved to treat patients with advanced or unresectable melanoma who progressed on previous ipilimumab therapy and, if applicable, a BRAF inhibitor. Each agent has received FDA approval for flat dosing (pembrolizumab 200 mg every 3 weeks or 400 mg every 6 weeks; nivolumab 240 mg every 2 weeks or 480 mg every 4 weeks) based on dose/exposure, efficacy, and safety data.

⑥ Like ipilimumab, the response to PD-1 inhibitors is delayed but the response to PD-1 inhibitors may be slightly faster than with ipilimumab. The irAE profile with PD-1 inhibitors is different, with the most common adverse drug reactions with pembrolizumab and nivolumab being fatigue, cough, nausea, pruritus, rash, decreased appetite, constipation, arthralgias, and diarrhea.[41,42] The risk of grade 3 or 4 irAEs is significantly lower as compared to ipilimumab. Specifically, the incidence of grade 3 or 4 diarrhea/colitis with PD-1 inhibitors is dramatically lower and occurs in only 1% to 2% of patients. However, a higher incidence of autoimmune pneumonitis (1%-2%) is seen with nivolumab and pembrolizumab as compared to ipilimumab.[27] Patients should be counseled to notify a clinician if they notice new or worsening cough, chest pain, or shortness of breath. Treatment of irAEs follows the same established treatment algorithms as ipilimumab (Table 162-6).

First-line therapy with PD-1 inhibitors has been evaluated to treat unresectable or metastatic melanoma. In the KEYNOTE-006 trial, pembrolizumab was compared directly to ipilimumab for first-line treatment. In this trial, 834 patients with unresectable or metastatic melanoma were randomized to receive pembrolizumab 10 mg/kg every 2 weeks or every 3 weeks or ipilimumab 3 mg/kg every 3 weeks for four doses. One-year overall survival rates were 75% for the pembrolizumab every 2 weeks, 68.4% for the pembrolizumab every 3 weeks, and 58.2% for ipilimumab.[43] Treatment-related grade 3 or 4 adverse effects were lower in both pembrolizumab arms. With better efficacy and less toxicity compared to ipilimumab, the FDA-approved pembrolizumab 2 mg/kg IV every 3 weeks as a first-line treatment option for metastatic melanoma. Similarly, in a randomized controlled trial comparing nivolumab with dacarbazine for first-line treatment of BRAF wild-type metastatic melanoma, nivolumab produced significantly better 1-year overall survival rates, median progression-free survival, and overall response rates.[44] The NCCN Guidelines recommend both pembrolizumab and nivolumab as preferred first-line treatment options for patients with unresectable or metastatic disease.[8]

Combination CTLA-4 and PD-1 Inhibitors

⑤ ⑥ The combination of a CTLA-4 inhibitor, which stimulates the immune system at the central level in the priming phase of T-cell activation and proliferation, and a PD-1 inhibitor, which acts in the peripheral phase within the tumor microenvironment, can result in synergistic activity. Survival rates of 90% at 1 year and >80% at 2 years were unprecedented in the treatment of metastatic melanoma in early trials.[8] This combination was studied in the landmark Checkmate-067 trial, which included 945 previously untreated patients with unresectable stage III or IV melanoma. Patients were randomized to receive either nivolumab 3 mg/kg alone, nivolumab 1 mg/kg plus ipilimumab 3 mg/kg, or ipilimumab 3 mg/kg alone. The median progression-free survival was 11.5 months with nivolumab plus ipilimumab, compared with 6.9 months with nivolumab alone and 2.9 months with ipilimumab alone.[45] After 6.5 years of follow-up, the median overall survival with the combination is 72.1 months, 36.9 months with nivolumab alone, and 19.9 months with ipilimumab alone.[46] Of particular importance, 81% of patients who received the combination were off treatment and never received subsequent systemic therapy, highlighting the durability of treatment responses. A second trial, CheckMate-069, confirmed the benefits of this combination. In this double-blind, randomized, controlled trial, 142 untreated melanoma patients were randomized to receive ipilimumab 3 mg/kg plus nivolumab 1 mg/kg or the same dose of ipilimumab with placebo once every 3 weeks for four doses. Patients then received nivolumab (ipilimumab arm) or placebo at the same dose every 2 weeks until disease progression or unacceptable toxicity.[47] The objective response rate was 61% for patients receiving the combination versus 11% for patients receiving ipilimumab alone. Complete responses were seen in 22% of the combination arm with none in the ipilimumab arm and responses were seen regardless of *BRAF* mutational status. Median progression-free survival was significantly longer in the combination arm. As with previous studies, the responses were durable, with 82% of responding patients in the combination arm maintaining their response.[47]

One of the most significant concerns with a combination of two immune checkpoint inhibitors is the safety profile. In Checkmate-067, grade 3 or 4 treatment-related adverse drug reactions were significantly higher with the combination arm than nivolumab or ipilimumab alone.[45] Similar safety results were observed in Checkmate-069, with grade 3 or 4 drug-related adverse reactions occurring more frequently in the combination arm than ipilimumab alone.[47] As a result of the data from these two trials, the FDA granted approval for combination therapy with nivolumab 1 mg/kg plus ipilimumab 3 mg/kg every 3 weeks for four doses followed by nivolumab maintenance (240 mg every 2 weeks or 480 mg every 4 weeks) in patients with unresectable or metastatic melanoma. While this combination offers higher response rates with the potential for durable responses, judicious monitoring and aggressive management of toxicities are important.

Summary of Immune Checkpoint Inhibitors

Over the last decade, advances in immunotherapy have provided new treatment options and offered new hope regarding survival for patients with metastatic melanoma. These benefits are realized with single-agent or combination immune checkpoint inhibitors. Despite advances in the treatment of melanoma, several questions still surround the use of immunotherapy. First, how do we identify which patients will benefit from immunotherapy treatment? Some clinicians are hesitant to treat older patients or those with autoimmune conditions with ipilimumab because of toxicity concerns. These unique patient populations require further investigation. Second, what are the biomarkers of response to immunotherapy? Immunologic markers and other biomarkers have been investigated without success.[48] Tumors that express PD-L1, regardless of the type of cancer, have demonstrated higher responses to PD-1/PD-L1 blockade. However, patients with tumors that do not express PD-1/PD-L1 may also benefit and should not be excluded from this treatment option. In addition, it remains unclear as to the best approach for assessing PD-L1 expression, definition of positivity in the assay, and clinical application.[40] Lastly, what is the optimal sequencing of systemic therapy with immunotherapy and targeted therapy? A recent study (DREAMseq) evaluated the sequencing of initial treatment with combination immunotherapy versus combination targeted therapy. Patients with untreated *BRAF* V600-mutant metastatic melanoma were randomized to receive initial therapy with nivolumab and ipilimumab or dabrafenib and trametinib; patients were crossed over to the alternate combination at progression. Initial overall response rates were similar at 46%

with nivolumab and ipilimumab versus 43% with dabrafenib and trametinib. However, 88% of patients who responded to nivolumab and ipilimumab remained in response compared to 49% of those who responded to dabrafenib and trametinib. In addition, response rates to nivolumab and ipilimumab were lower in the second-line setting, which suggests that combination immunotherapy is less effective after progression on dabrafenib and trametinib. A meaningful difference in overall survival was observed. At a median follow-up of 27.7 months, overall survival for the nivolumab and ipilimumab group was 72% compared to 52% for dabrafenib and trametinib, a 20% absolute difference in survival.[49] These results suggest that the combination of nivolumab and ipilimumab is preferred as initial therapy over BRAF and MEK inhibitor combination therapy.

Other Immunotherapy Approaches

Vaccine therapy has been investigated for over a decade in metastatic melanoma. The rationale for vaccination is that antigens expressed on the surface of tumor cells differ from normal cells and a vaccine has the ability to induce effective tumor-specific immune responses with less toxicity than conventional chemotherapy or other immunotherapies.

A variety of melanoma vaccines, based on whole tumor cells, peptides, and proteins have been evaluated to treat patients with metastatic disease or intermediate-risk and high-risk patients following surgical resection. To date, no vaccine has shown a survival advantage.[11] Occasional clinical responses have been observed in trials of melanoma vaccines. Vaccines in combination with other biologic therapies have been evaluated. Although early efficacy signals have been seen with some combination approaches, none have improved survival.[11] Clinical trials that incorporate vaccines into approved immunotherapeutic treatments are ongoing.

Oncolytic immunotherapy has been investigated for the treatment of metastatic melanoma. Talimogene laherparepvec (T-VEC) is a genetically modified oncolytic virus derived from herpes simplex-1. T-VEC works by two distinct mechanisms: (1) modification of attenuated HSV-1 to selectively replicate within tumor cells causing death while sparing other cells and (2) secretion of GM-CSF to attract dendritic cells to the site for antigen presentation and T-cell activation. Activated T cells can then target the cancer cells systemically. In a phase III study, T-VEC demonstrated better response rates (including complete responses) and a trend toward improved survival compared to GM-CSF alone.[50] It was well tolerated with fatigue, chills, and fever being the most common adverse drug reactions with few severe events reported. T-VEC is FDA approved for the local treatment of unresectable cutaneous, subcutaneous, and nodal lesions in patients with recurrent melanoma after initial surgery. T-VEC is administered intratumorally (injected directly into the tumor) and therefore patients with internal visceral disease are not appropriate candidates for treatment. With its favorable toxicity profile, T-VEC has been studied in combination with other immunotherapies. Masterkey-265 was a phase III, randomized, double-blind study evaluating the use of TVEC plus pembrolizumab versus pembrolizumab alone in unresectable or metastatic melanoma. Unfortunately, the combination did not significantly improve progression-free or overall survival, indicating that TVEC did not add any additional benefit to PD-1 inhibitor monotherapy.[51]

Targeted Therapy

7 Oral kinase inhibitors have emerged as standard therapy for malignancies such as renal cell carcinoma, chronic myelogenous leukemia, subsets of lung cancer, and gastrointestinal stromal tumors. As our understanding of the biology of melanoma grows, there is increasing interest in developing therapies against molecular targets involved in the development and progression of melanoma. Several orally administered targeted therapies are FDA approved to treat melanoma (see Tables 162-7 and 162-8).

TABLE 162-7

Dosing of BRAF Inhibitors in Melanoma

Drug	Brand Name	Dose	Dose Reductions for Adverse Drug Reactions	Food-Drug Interaction	Drug-Drug Interactions
Dabrafenib	Tafinlar	- 150 mg BID - Missed dose may be taken up to 6 hours prior to	- First: 100 mg BID - Second: 75 mg BID - Third: 50 mg BID - Subsequent:	- Take at least 1 hour before or 2 hours after a meal	- Dabrafenib may decrease drug levels of CYP2B6, CYP2C19, CYP2C8, CYP2C9, and CYP3A4 substrates - Strong CYP2C8 and CYP3A4 inhibitors

		next dose	permanently discontinue if unable to tolerate 50 mg BID	• High-fat meals decrease C_{max} and AUC	may increase dabrafenib concentrations • Concurrent use with antacids, H2-antagonists, and proton pump inhibitors may decrease dabrafenib concentrations • Concurrent use with St. John's wort may decrease dabrafenib concentrations • Monitor closely if dabrafenib is used concurrently with other drugs known to prolong QT interval
Encorafenib	Braftovi	• 450 mg daily • Missed dose may be taken up to 12 hours prior to next dose	• First: 300 mg daily • Second: 200 mg daily • Subsequent: permanently discontinue if unable to tolerate 200 mg daily	• Take with or without food • Avoid grapefruit juice	• Strong and moderate CYP3A4 inhibitors may increase encorafenib concentrations • Reduce encorafenib dose to one-third original dose if used concurrently with strong CYP3A4 inhibitor • Reduce encorafenib dose to one-half original dose is used concurrently with moderate CYP3A4 inhibitor • Strong or moderate CYP3A4 inducers may decrease encorafenib concentrations • Encorafenib may increase toxicity or decrease efficacy of sensitive CYP3A4 substrates • Coadministration with hormonal contraceptives can result in decreased concentrations and loss of efficacy • Avoid coadministration of encorafenib with other drugs known to prolong QTc interval
Vemurafenib	Zelboraf	• 960 mg BID • Missed dose may be taken up to 4 hours prior to next dose	• First: 720 mg BID • Second: 480 mg BID • Subsequent: permanently discontinue if unable to tolerate 480 mg BID	• Take with or without food • Avoid grapefruit juice	• Avoid concomitant administration with CYP1A2 substrates with a narrow therapeutic window • Strong CYP3A4 inhibitors/inducers may increase/decrease vemurafenib concentrations and should be avoided • Vemurafenib may increase concentrations of CYP2D6 substrates • Avoid concurrent use with P-gp substrates known to have narrow therapeutic indices • Monitor closely if vemurafenib is used concurrently with other drugs known

					to prolong QT interval

AUC, Area under the curve; CYP, cytochrome P450.

TABLE 162-8

Dosing of MEK Inhibitors in Melanoma

Drug	Brand Name	Dose	Dose Reductions for Adverse Drug Reactions	Food-Drug Interaction	Drug-Drug Interactions
Binimetinib	Mektovi	• 45 mg BID • Missed dose may be taken up to 6 hours prior to the next dose	• First: 30 mg BID • Subsequent: permanently discontinue if unable to tolerate 30 mg BID	• Take with or without food	• No known significant interactions
Cobimetinib	Cotellic	• 60 mg daily on days 1-21 of 28-day cycle	• First: 40 mg daily • Second: 20 mg daily • Subsequent: permanently discontinue if unable to tolerate 20 mg daily	• Take with or without food	• CYP3A4 inducers may decrease cobimetenib concentrations • CYP3A4 inhibitors may increase cobimetenib concentrations
Trametinib	Mekinist	• 2 mg daily • Store in the refrigerator (36-46°F [2-8°C]) • Missed dose may be taken up to 12 hours prior to the next dose	• First: 1.5 mg daily • Second: 1 mg daily • Permanently discontinue if unable to tolerate 1 mg daily	• Take at least 1 hour before or 2 hours after a meal • High-fat meals may decrease AUC	• May enhance the adverse effects of dabrafenib

AUC, Area under the curve; CYP, cytochrome P450.

Vemurafenib was the first BRAF inhibitor developed to treat patients with metastatic melanoma who harbor a V600E mutation. In a phase III trial comparing vemurafenib with dacarbazine in patients with unresectable, previously untreated stage IIIC or IV melanoma with a *BRAF* V600E mutation, vemurafenib significantly improved response rate and overall survival. Patients treated with vemurafenib had longer median progression-free survival and a higher overall survival rate at 6 months. The median time-to-response was also shorter with vemurafenib than dacarbazine.[8]

Dabrafenib, another oral selective BRAF inhibitor, demonstrated similar activity to vemurafenib in early-stage clinical trials in patients with previously untreated *BRAF* V6000E mutated melanoma. In a phase III study, dabrafenib was compared to dacarbazine in patients with untreated stage IV or unresectable stage III melanoma. Patients in the dabrafenib arm had longer median progression-free survival. A follow-up analysis showed that overall survival at 12 months was 70% with dabrafenib as compared to 63% with dacarbazine.[8] Both vemurafenib and dabrafenib have been studied in melanoma patients with CNS metastasis with some activity. Other targeted agents, such as the pan-RAF inhibitor sorafenib, have historically been studied in this setting without encouraging results.[8]

BRAF inhibitors are generally well tolerated (see Table 162-9). Skin complications, comprising of cutaneous squamous cell carcinoma or keratoacanthoma and photosensitivity reactions, are a major concern with the use of these agents. In clinical trials, the incidence of cutaneous squamous cell carcinoma or keratoacanthoma with vemurafenib was 18% and 6% with dabrafenib. The development of these lesions result from the activation of the MAPK pathway in healthy skin cells lacking *BRAF* alterations. As a result, patients receiving a BRAF inhibitor should have dermatologic evaluations prior to starting therapy, every 2 months while on therapy and for up to 6 months following discontinuation of therapy. Cutaneous complications can be effectively managed by surgical resection and treatment with the BRAF inhibitor can continue without dose adjustment.[52]

TABLE 162-9

Monitoring of BRAF Inhibitors in Melanoma

Drug	Adverse Drug Reactions		Monitoring Parameters	Comments
	Common	Rare but Serious		
Dabrafenib	• Pyrexia • Rash • Chills • Headache • Arthralgia • Fatigue • Hyperkeratosis • Nausea/vomiting/diarrhea • Alopecia • Palmar-plantar erythrodysesthesia • Increased LFTs • Hyperglycemia • Hypophosphatemia	• New primary malignancies (cutaneous and noncutaneous) • Hemorrhage • Uveitis • Pancreatitis • Interstitial nephritis	• CMP including serum phosphorus, albumin, glucose, and LFTs • CBC for myelosuppression • Dermatologic examinations at baseline, every 2 months during treatment, then 6 months after discontinuation for secondary skin malignancies • ECG for QT prolongation • Signs/symptoms of uveitis (vision changes, photophobia, eye pain)	• Risk of secondary skin malignancies decreases when used in combination with MEK inhibitor • ECHO to assess LVEF when used in combination with MEK inhibitor • Patients with G6PD deficiency are at risk for hemolytic anemia
Encorafenib	• Fatigue • Nausea/vomiting • Abdominal pain • Arthralgia • Rash • Myopathy • Hyperkeratosis • Headache • Anemia • Increased LFTs • Pyrexia	• New primary malignancies (cutaneous and noncutaneous) • Hemorrhage • Uveitis • QTc prolongation	• Dermatologic evaluation prior to, while on therapy, and following discontinuation of treatment • CMP including serum phosphorus, magnesium, glucose, and LFTs • ECG for QT prolongation; electrolytes before and during treatment • Signs/symptoms of uveitis (vision changes, photophobia, eye pain)	• Only FDA approved in combination with binimetinib • If binimetinib is held, the encorafenib dose must be reduced to 300 mg daily
Vemurafenib	• Arthralgia • Rash • Alopecia • Fatigue • Nausea • Photosensitivity • Pruritus • Skin papilloma	• New primary malignancies (cutaneous and noncutaneous) • Uveitis • QTc prolongation • Severe dermatologic reactions (SJS,	• LFTs at baseline and monthly or as clinically indicated • Serum creatinine at baseline and periodically during treatment • ECG and electrolytes (including potassium, magnesium, and calcium) at baseline, after 15 days, monthly for the first 3 months, then every 3 months or as clinically indicated • Dermatologic examinations at baseline,	• Off-label indication for *BRAF* V600K mutation • Associated with rare cases of pancreatitis; evaluate unexplained abdominal pain • Due to photosensitivity, patients should avoid

		TEN) • Hypersensitivity reactions (including DRESS) • Renal failure	every 2 months during treatment. Consider monitoring for 6 months following discontinuation • Signs/symptoms of uveitis (vision changes, photophobia, eye pain) • Monitor closely if administered concomitantly or sequentially with radiation treatment	the sun, wear protective clothing, and wear sunscreen

CMP, comprehensive metabolic panel; CBC, complete blood count; CPK, creatine phosphokinase; DVT, deep vein thrombosis; DRESS, drug reaction with eosinophilia and systemic symptoms; LFT's, liver function tests; LVEF, left ventricular function; PE, pulmonary embolism.

Resistance to BRAF inhibitors is potentially caused by mutations in *MEK*, dependency on MEK/ERK antiapoptotic signaling, PI3K/AKT pathway involvement, *NRAS* mutation, or MAPK pathway reactivation. Concurrent treatment with an MEK inhibitor in combination with a BRAF inhibitor can delay the onset of acquired resistance.

7 MEK inhibitors have been studied in the treatment of metastatic melanoma and have shown modest activity as monotherapy. Trametinib is an oral small-molecule inhibitor of MEK1/2 that was studied in a phase III trial that compared trametinib to chemotherapy (dacarbazine or paclitaxel). In this trial, median progression-free survival was 4.8 versus 1.5 months in the trametinib and chemotherapy arms, respectively. Overall survival at 6 months was 81% for trametinib and 67% for chemotherapy, even with crossover at progression. Common adverse drug reactions seen with trametinib were rash, diarrhea, and peripheral edema (see Table 162-10). Interestingly, secondary skin neoplasms were not observed in this trial.[8]

TABLE 162-10

Monitoring of MEK Inhibitors in Melanoma

Drug	Adverse Drug Reactions		Monitoring Parameters	Comments
	Common	Rare but Serious		
Binimetinib	• Fatigue • Nausea/vomiting • Abdominal pain • Diarrhea • Constipation • Rash • Increased LFTs • Anemia • Increased creatinine • Increased CPK • Hyponatremia	• VTE • Cardiomyopathy • Ocular toxicity (serous retinopathy/retinal pigment epithelial detachments, retinal vein occlusion) • Interstitial lung disease/pneumonitis • New primary malignancies (cutaneous and noncutaneous) • Hemorrhage • Rhabdomyolysis	• LFTs at baseline, monthly during treatment, and as clinically indicated • CPK and serum creatinine at baseline, periodically during treatment, and as clinically indicated • Assess for visual symptoms at each visit. Perform ophthalmologic examination at regular intervals and for any new/worsening visual disturbances • Signs and symptoms of bleeding • LVEF at baseline, 1 month after therapy initiation, then at 2- to 3-month intervals for cardiomyopathy • Evaluate for signs/symptoms of pulmonary toxicity (cough,	• If encorafenib is permanently discontinued, discontinue binimetinib • Serous retinopathy occurred in 20% of patients treated with binimetinib in combination with encorafenib • Elevation in LFTs can occur with combination; monitor prior to beginning treatment and monthly during treatment

			dyspnea, hypoxia, pleural effusions, infiltrates)	
Cobimetinib	• Nausea/vomiting • Diarrhea • Hypertension • Photosensitivity • Pyrexia • Hypophosphatemia • Electrolyte disturbances • Hypoalbuminemia • Lymphopenia • Anemia • Increased LFTs • Increased CPK • Increase in serum creatinine • Hyponatremia	• Cardiomyopathy • Hemorrhage • New primary malignancies (cutaneous and noncutaneous) • Ocular toxicity (serous retinopathy, retinal vein occlusion • Hepatotoxicity • Rhabdomyolysis	• CMP at baseline and monthly during treatment for hepatotoxicity, renal failure, and electrolyte replacement • CPK at baseline, periodically during treatment, and as clinically indicated • LVEF at baseline, 1 month after initiation of therapy, and every 3 months until discontinuation • Dermatologic examinations at baseline, every 2 months during treatment, then 6 months after discontinuation for secondary skin malignancies • Ophthalmological evaluation at regular intervals and at any sign of new or worsening visual disturbances • Signs and symptoms of hemorrhage and rhabdomyolysis	• Due to photosensitivity, patients should avoid the sun, wear protective clothing, and wear sunscreen • Hypertension has been seen in combination with vemurafenib
Trametinib	• Dermatologic toxicity (rash, acneiform dermatitis, palmar-plantar erythrodysesthesia, erythema) • Diarrhea • Lymphedema (including edema, peripheral edema) • Pyrexia • Hypertension • Fatigue • Nausea/vomiting • Hyperglycemia • Increased LFTs • Anemia • Hypoalbuminemia	• VTE • Cardiomyopathy • Ocular toxicity (retinal pigment epithelial detachments, retinal vein occlusion) • Interstitial lung disease/pneumonitis • New primary malignancies (cutaneous and noncutaneous) • Hemorrhage • Colitis/GI perforation • Rhabdomyolysis	• CBC and CMP at baseline and as clinically indicated • LVEF at baseline, 1 month after therapy initiation, then at 2- to 3-month intervals • Ophthalmological evaluation periodically and at any sign of visual disturbance • Evaluate for signs/symptoms of pulmonary toxicity (cough, dyspnea, hypoxia, pleural effusions, infiltrates) • Blood pressure • Signs and symptoms of bleeding • Dermatologic examinations at baseline, every 2 months during treatment, then 6 months after discontinuation • Monitor closely for colitis and GI perforation	• Severe skin toxicities can require hospitalization • Intracranial hemorrhage can be fatal • Many adverse effects are increased when trametinib is used in combination with dabrafenib • Increased incidence of DVT/PE when used in combination with dabrafenib • Increase in serious febrile reactions when used in combination with dabrafenib

CMP, comprehensive metabolic panel; CBC, complete blood count; CPK, creatine phosphokinase; DVT, deep vein thrombosis; DRESS, drug reaction with eosinophilia and systemic symptoms; LFT's, liver function tests; LVEF, left ventricular function; PE, pulmonary embolism; VTE, venous thromboembolism.

In addition to delaying drug resistance, the combination of BRAF and MEK inhibitors shows additive efficacy in the treatment of melanoma. The combination of trametinib 2 mg orally once daily and dabrafenib 150 mg orally twice daily received accelerated approval for treatment in patients with unresectable or metastatic melanoma with *BRAF* V600 mutations based on higher objective response rates compared to either agent alone. Additional trials with this combination compared to BRAF inhibitors in the same patient population confirmed early findings and led to a full FDA approval. In a clinical trial that compared the combination to dabrafenib alone, patients randomized to the combination had longer median progression-free survival, overall survival at 6 months and higher overall response rates as compared with dabrafenib alone.[53] In another phase III trial, the combination of dabrafenib and trametinib showed significantly longer median overall survival and higher overall survival at 12 months. Median progression-free survival was also significantly longer and the overall response rate was higher in patients treated with the combination.[54] The safety profile with the combination was similar to that observed with either drug given alone, with the notable exception of decreased incidence of skin complications in the combination arms.

Cobimetinib is another inhibitor of MEK1/2 approved in combination with vemurafenib to treat patients with unresectable or metastatic melanoma with a *BRAF* V600E or V600K mutation. The recommended dosing with this regimen is vemurafenib 960 mg orally twice daily on days 1 to 28 and cobimetinib 60 mg orally once daily on days 1 to 21 of a 28-day cycle. In a phase III trial, median progression-free survival was significantly improved with the combined regimen of cobimetinib and vemurafenib versus vemurafenib alone. The difference in median overall survival was also statistically significant in favor of the combination. Overall response rates were 70% and 50% for the combination and single-agent arms, respectively. Adverse drug reactions were similar across the two groups and similar to the other MEK and BRAF combination, the number of secondary cutaneous cancer was decreased.[55]

The safety and efficacy of encorafenib and binimetinib, a BRAF and MEK inhibitor combination, were established in the COLUMBUS trial, a phase III study where 577 patients were randomized to receive encorafenib 450 mg daily plus binimetinib 45 mg twice daily, encorafenib 300 mg daily, or vemurafenib 960 mg twice daily. Median progression-free survival was significantly longer with the combination as compared with vemurafenib alone. The overall response rate was higher with encorafenib and binimetinib as compared to BRAF inhibitor monotherapy. The median overall survival was 33.6 months for the combination of encorafenib and binimetinib as compared to 16.9 months with vemurafenib. This is the longest overall survival observed of all studies conducted with combination BRAF and MEK inhibitors. The adverse drug reactions seen with encorafenib and binimetinib are similar to those of other BRAF and MEK inhibitor combinations.[56]

Another agent of interest in the treatment of metastatic melanoma is imatinib mesylate, an oral agent that inhibits *KIT* and platelet-derived growth factor receptor. *KIT* is expressed primarily in acral and mucosal melanomas and treatment with imatinib showed activity against melanoma cell growth in preclinical studies. In clinical trials with unselected patients, imatinib did not show benefit in metastatic melanoma despite downregulation of phosphorylated *KIT*.[8] However, a phase II trial of imatinib in patients with *KIT* mutations reported that 23% had a partial response, 30% had stable disease, and progression-free survival was 3.5 months.[8] Responses in these patients were short, similar to what is seen with BRAF inhibitor monotherapy. Other potential molecular targets in the treatment of melanoma include vascular endothelial growth factor and cyclin-dependent kinases. Studies with drugs that inhibit these pathways are ongoing.

Combination Targeted Therapy plus Immunotherapy

With the success of both immunotherapy and targeted therapy, combining agents from both classes is another area of great interest and ongoing research interest. Studies combining ipilimumab with BRAF inhibitors have been conducted but are associated with significant toxicity. A phase I trial combining vemurafenib and ipilimumab showed high rates of hepatotoxicity while case reports of dabrafenib/trametinib plus ipilimumab resulted in severe gastrointestinal toxicity, specifically perforation. Based on these results, the use of targeted therapy in combination with ipilimumab is not recommended.[8]

The combination of BRAF and MEK inhibitors plus other immune checkpoint inhibitors has shown promising results in the treatment of metastatic melanoma. IMspire150, a Phase III, double-blind study, randomized 514 patients with untreated *BRAF* V600-mutated metastatic melanoma to receive combination BRAF and MEK inhibitors (vemurafenib and cobimetinib) and either atezolizumab or placebo. At a median follow-up of 18.9 months, the median progression-free survival was significantly longer in patients treated with combination BRAF and MEK inhibitors and atezolizumab versus combination BRAF and MEK inhibitors alone (15.1 vs 10.6 months). Common treatment-related adverse drug reactions that occurred more frequently in the atezolizumab arm were increased blood creatinine phosphokinase, pyrexia, arthralgia, myalgia, increased liver enzymes and bilirubin, hyper/hypothyroidism, pneumonitis, pruritus, and peripheral edema.[57] Based on this study, the combination of vemurafenib, cobimetinib and atezolizumab was FDA-approved for the treatment of patients with *BRAF* V600 mutation-positive unresectable or metastatic melanoma and is also recommended per the NCCN guidelines in this treatment setting.[8] The dosing for this regimen includes a run-in period with vemurafenib 960 mg by mouth twice daily for 21 days then 720 mg twice daily thereafter plus cobimetinib 60 mg daily days 1 to 21 every 28 days in addition to atezolizumab 840 mg IV every 2 weeks. Another BRAF and MEK inhibitor combination (dabrafenib and trametinib) has also been studied in combination with immunotherapy. Keynote-022 was a double-blind, phase II study evaluating the use of dabrafenib and trametinib and either pembrolizumab or placebo for patients with untreated *BRAF* V600-mutated advanced melanoma. This study showed that at 36.6 months of follow-up, the addition of immunotherapy to combination BRAF and MEK inhibitor therapy substantially improved progression-free survival, duration of response, and overall survival but with a higher incidence of treatment-related adverse drug reactions. These results show the importance of careful patient selection to identify the best candidates for combined modality therapy.[58]

Radiation

The role of radiation in the adjuvant treatment of melanoma has been investigated. Recent data from a prospective study suggest patients treated with therapeutic lymphadenectomy for lymph node relapse benefit from postoperative radiation to the nodal basins as compared to observation. Lymph node recurrence was significantly less in the adjuvant radiation arm, but increased toxicity was noted. No difference in overall survival or relapse-free survival was observed between the groups.[59] Adjuvant radiation may be an acceptable option for selected patients. Radiation can also be used in patients with in-transit metastasis, satellite metastasis, or for extranodal tumor extension. For patients with metastatic melanoma, radiation is palliative to symptomatic areas of disease progression. Stereotactic radiosurgery (SRS), or stereotactic radiotherapy (SRT), is the preferred type of treatment for brain metastases. Adjuvant radiation, given after resection of brain metastases, can help with disease control. Whole brain radiation is associated with worse cognitive decline compared to SRS/SRT, and therefore should be used in situations when SRS/SRT is not achievable.[60] Whole brain radiation may be needed in situations that involve numerous brain metastasis or leptomeningeal disease.

Limb Perfusion and Limb Infusion

Isolated limb perfusion is a surgical procedure involving regional intravascular delivery of chemotherapy or biotherapy (or both) into an extremity with cutaneous melanoma. When in-transit metastases occurs in extremities, local therapy with isolated limb perfusion or isolated limb infusion has been used.[8] Isolated limb perfusion is a method for escalating the dose of chemotherapeutic drugs to a specific region of the body while limiting the systemic toxicities of the agent. Most perfusions can be performed with drug exposures of less than 2%. The most significant adverse drug reaction of isolated limb perfusion is regional toxicity because the skin, subcutaneous tissue, and tissue of the extremity receives the same dose and is subjected to the same perfusion conditions as the tumor located within the extremity. After regional perfusions, objective response rates greater than 50% in treated limbs have been reported, with overall response rates possibly as high as 80%. Although most clinical trials have used melphalan, it is not known whether the combination of melphalan with other agents may improve results.[8] This is also a technically complex procedure that should only be performed at centers with the proper clinical expertise. A simplified form of isolated limb perfusion, called isolated limb infusion, is a low-flow isolated limb perfusion performed under hypoxic conditions via small-caliber arterial and venous catheters. It has been proposed that the hypoxia which develops during isolated limb infusion may be beneficial with certain cytotoxic agents such as melphalan.[8]

EVALUATION OF THERAPEUTIC OUTCOMES

The outcome of patients treated with melanoma depends on the stage of disease at presentation. The prognosis of patients with thin tumors (less than 1 mm in thickness) and localized disease is good with long-term survival in more than 90% of patients. The risk of regional nodal involvement rises with increasing tumor thickness and survival rates decrease in patients with nodal involvement. Long-term survival in patients with distant metastasis is even lower. Therefore, early diagnosis and appropriate treatment of early disease are essential. Patients with suspicious pigmented lesions should be evaluated and the lesion excised whenever possible. Treatment is determined by patient factors and stage of disease.

Clinical practice guidelines published by the NCCN and European Society of Clinical Oncology (ESMO) provide guidance for treatment and follow-up of patients with melanoma.[8,61] Intensive surveillance has the benefit of early detection of recurrent disease, which may lead to better options for surgical resection. Emphasis on the evaluation of locoregional areas is important. For patients with in situ melanoma, periodic skin examinations for life are recommended, with frequency determined based on patient risk factors. Local recurrence is associated with aggressive tumor biology and frequently is a manifestation of an aggressive primary tumor. If a local recurrence occurs after inadequate primary disease management, the patient should undergo a workup based on the lesion thickness of the original melanoma. Patients with nodal recurrence should be evaluated for lymph node metastasis. Patients with systemic recurrence should be evaluated and treated similarly to patients presenting with systemic disease.

CONCLUSION

Treatment of cutaneous melanoma is determined by both disease-related and patient-related issues. Treatment recommendations are based on stage of disease. Treatment of localized disease is surgical excision, with the extent of excision based on the tumor size. Wide excision is recommended for in situ melanoma and wide excision with SLNB for stage IA, IB, and II disease.

The addition of new immunotherapy and targeted agents has increased the number of adjuvant treatment options for patients with melanoma who are at high risk of recurrence. Identifying which patients are appropriate candidates for treatment after resection of the primary tumor remains a challenge. When choosing an adjuvant treatment, the clinician should consider patient preference, age, comorbidities, and risk of recurrence.[8]

⑧ Due to the rapid influx of effective therapies, the management of metastatic melanoma has become complex. The NCCN guidelines list a variety of preferred systemic therapies for advanced or metastatic melanoma, including ipilimumab/nivolumab, pembrolizumab, nivolumab, combination BRAF and MEK inhibitors, triple therapy with BRAF and MEK inhibitors plus PD-1 (or PD-L1) inhibitor, ipilimumab, high-dose aldesleukin, and in certain cases chemotherapy or other targeted agents.[8] The choice of drug therapy should be based on *BRAF* mutational status, the aggressiveness of the disease, and disease-related symptoms. Patients with a more indolent clinical picture may respond better to immunotherapy. Patients with a documented *BRAF* mutation are candidates for treatment with a BRAF and MEK inhibitor combination regimen. Best supportive care is also an option for some individuals. Surgical treatment of metastatic melanoma should be considered in select individuals based on the extent and location of disease and performance status.

Chapter 164: Assessment of Nutrition Status and Nutrition Requirements

Katherine Hammond Chessman; Angela L. Bingham

KEY CONCEPTS

KEY CONCEPTS

① Malnutrition encompasses both undernutrition and overnutrition (obesity); although, the term is most often used to refer to undernutrition.

② Nutrition screening is distinct from nutrition assessment; an effective screening process should be designed to identify quickly and consistently those with pre-existing malnutrition or those at risk for malnutrition.

③ A comprehensive medical, surgical, and dietary history; a nutrition-focused physical examination (NFPE); and anthropometric and laboratory measurements are essential components of a comprehensive nutrition assessment.

④ Anthropometrics, physical measurements of the size, weight, and proportions of the human body, are important parameters used to assess nutrition status.

⑤ Laboratory assessment of nutrition status must be interpreted in the context of clinical status and acute and chronic inflammation.

⑥ Macronutrient or micronutrient deficiencies or toxicities or risk factors for these deficiencies or toxicities can be identified by a comprehensive nutrition assessment.

⑦ Evidence-based patient-specific goals should be established considering the patient’s clinical condition and the need for maintenance or repletion in adults and continued growth and development in children.

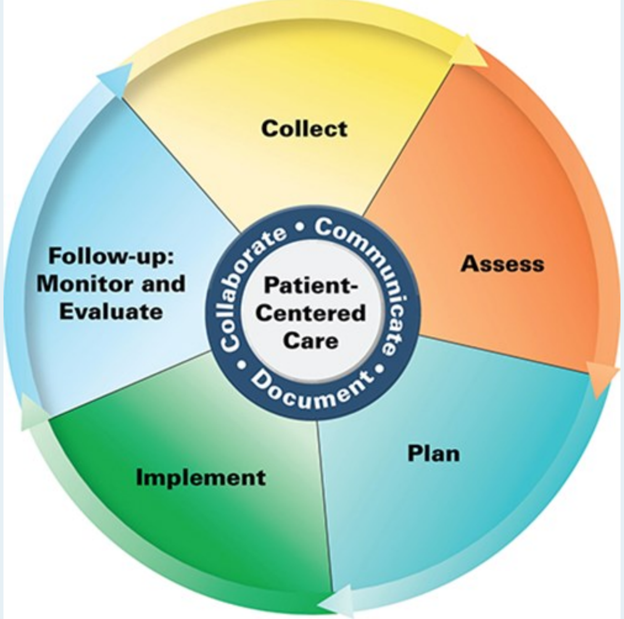
⑧ Validated predictive equations and population estimates are most often used to determine energy requirements; however, if available, indirect calorimetry is the most accurate bedside method to determine energy requirements.

⑨ Daily protein needs are based on age, sex, nutrition status, disease state, and clinical condition.

⑩ Drug–nutrient interactions can affect response to medication therapy and nutrition status.

PATIENT CARE PROCESS

Patient Care Process for Nutrition Screening and Assessment



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, diagnosis)
- Patient history (eg, medical, surgical, diet, recent GI losses, environmental exposures, alcohol use; see Tables 164-1, 164-2)
- Current medications, including nutrition supplements
- Objective data
  - Body weight (current and usual)
  - Stature, body mass index (BMI), head circumference
  - Recent dietary and fluid intake
  - Nutrition-focused physical exam (see Table 164-3)
  - Labs (eg, serum electrolytes; glucose; blood urea nitrogen/serum creatinine [SCr]; albumin, prealbumin; C-reactive protein [CRP]; liver function tests; vitamin, mineral, and trace element concentrations)

Assess

- Nutrition status: presence of malnutrition, obesity (see Table 164-4)
- Risk of refeeding syndrome (eg, unintentional weight loss of more than 5% to 10% of usual body weight, prolonged period with poor caloric intake, BMI less than 18.5 kg/m^2, loss of subcutaneous fat, loss of muscle mass, electrolyte abnormalities)
- Signs and symptoms of micronutrient deficiencies or toxicities (see Tables 164-7, 164-8)
- Determine nutrition requirements based on current clinical condition (see Tables 164-9, 164-10, 164-11, 164-12, 164-13, 164-14, 164-15)

Plan*

- Conduct indirect calorimetry to estimate energy needs, if appropriate
- Develop a nutrition care plan to ensure delivery of estimated nutrition needs (energy, protein, fluid, vitamins, trace elements)
- Develop a plan to avoid or manage potential drug-nutrient interactions (see Table 164-16)
- Develop a plan to monitor nutritional recovery
- Make referrals to other providers, when appropriate (eg, dietitian, speech therapist, wound care nurse, lactation specialist)

Implement[*]

- Provide nutrition support using estimated goals
- Provide nutrient supplements to correct deficiencies
- Restrict nutrients to avoid toxicities
- Provide patient education regarding all elements of the nutrition care plan

Follow-up: Monitor and Evaluate

- Appropriate weight gain, loss, or maintenance
- Appropriate gains in length and head circumference in children
- Maintenance or return of function, including muscle strength
- Laboratory parameters, as indicated
- Monitor for side effects of nutrition care
- Monitor for patient adherence to nutrition care plan

[*] *Collaborate with patient, caregivers, and other health care professionals*

INTRODUCTION

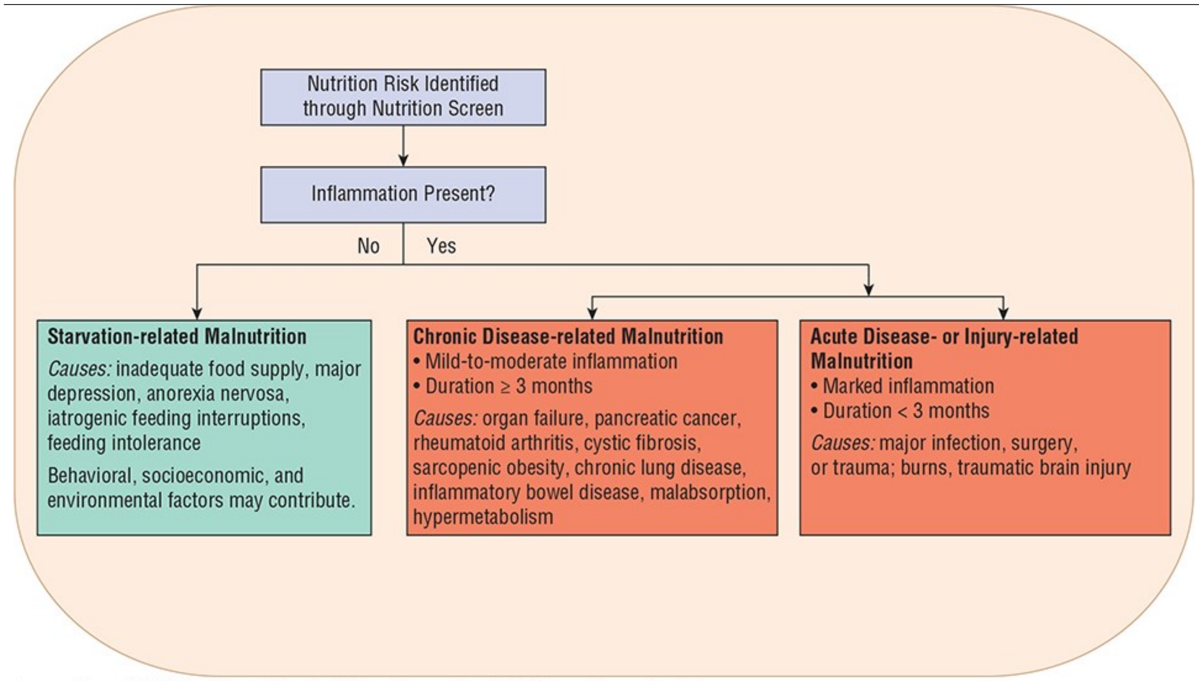
Nutrition care is an essential component of quality patient care. Nutrition screening and assessment are integral components of the nutrition care process. No single clinical or laboratory parameter is an absolute indicator of nutrition status, so information must be collected and analyzed from a number of sources. This chapter reviews tools most commonly used for accurate, relevant, and cost-effective nutrition screening and assessment, including various methods used to determine patient-specific macro- and micronutrient requirements, and potential drug–nutrient interactions (DNI).

CLASSIFICATION OF NUTRITION STATUS

① *Malnutrition* encompasses both undernutrition and overnutrition (obesity); although, the term is most often used to refer to undernutrition. Malnutrition is a consequence of nutrient imbalance. In general, deficiency states can be classified as those involving protein, energy, or single nutrients such as individual vitamins or trace elements. Many terms have been used to define malnutrition leading international nutrition experts to propose standardization of nomenclature and diagnosis for both adults and children.[1–3] Starvation-associated malnutrition, *marasmus*, results from prolonged inadequate intake, absorption, or utilization of protein and energy. It can occur in patients with an inadequate food supply, anorexia nervosa, major depression, and malabsorption syndromes (Fig. 164-1). Somatic protein (skeletal muscle) and adipose tissue (subcutaneous fat) wasting occurs, but visceral protein (albumin [ALB] and transferrin [TFN]) production is usually preserved. Moderate weight loss of 10% of usual body weight (UBW; typical weight) over a 6-month period is prognostic of poor clinical outcomes. A severe weight loss (30% or more of UBW) is life-threatening.[4] Patients with starvation-associated malnutrition commonly have a prototypical wasted appearance. When starvation-associated malnutrition develops as a consequence of primarily inadequate protein intake as is seen in areas of famine or limited food supply, affected individuals may not appear malnourished because of relative adipose tissue sparing, especially with mild undernutrition, but visceral (and to some degree somatic) protein stores are depleted, resulting in severe hypoalbuminemia and edema in more advanced cases. In patients with starvation-related malnutrition, enhancing nutritional intake or bypassing impaired absorption with nutrition support can reverse the condition. Careful nutritional resuscitation is required to avoid complications related to refeeding.[5]

FIGURE 164-1

Etiologic basis for malnutrition diagnosis. (*Data from References* 1 and 2.)



Nutrition Risk Identified through Nutrition Screen
Inflammation Present?
No
Yes
Starvation-related Malnutrition
Causes: inadequate food supply, major depression, anorexia nervosa, iatrogenic feeding interruptions, feeding intolerance
Behavioral, socioeconomic, and environmental factors may contribute.
Chronic Disease-related Malnutrition
• Mild-to-moderate inflammation
• Duration ≥ 3 months
Causes: organ failure, pancreatic cancer, rheumatoid arthritis, cystic fibrosis, sarcopenic obesity, chronic lung disease, inflammatory bowel disease, malabsorption, hypermetabolism
Acute Disease- or Injury-related Malnutrition
• Marked inflammation
• Duration < 3 months
Causes: major infection, surgery, or trauma; burns, traumatic brain injury

Malnutrition (undernutrition) may also develop as the result of an acute or chronic condition or disease, especially those associated with mild-to-severe inflammation (see Fig. 164-1).[1,2,4,6] Patients with severe acute disease or injury (major infections, burns, trauma) or with chronic inflammatory diseases (Crohn's disease), organ failure, or cancer can develop disease-related malnutrition because of increased metabolic demands despite seemingly adequate nutrition intake. Individuals with pre-existing starvation-related malnutrition can develop pronounced malnutrition if they experience a severe injury or inflammatory process. In patients with disease-related, acute or chronic, malnutrition, simply providing nutrients in usual or even increased amounts may not be sufficient to reverse the nutrient imbalance due to the chronic inflammatory process. As a patient's clinical course progresses, they may change from one malnutrition classification to another.[4] Regardless of the cause, malnutrition (undernutrition and overnutrition) can result in changes in subcellular, cellular, or organ function that increase morbidity and mortality.

Nutrition screening is also used to identify overnutrition: overweight and obese individuals and those at risk of becoming overweight or obese. Obesity is a major global healthcare concern; during 2017 to 2018, the age-adjusted prevalence of obesity (defined as a BMI ≥ 30 kg/m^2) was 42.4% and severe obesity (defined as a BMI ≥ 40 kg/m^2) was 9.2% of US adults.[7] In all states, more than 20% of adults were obese. Obesity prevalence in 2020 was 20% to 24.99% only in Colorado, Hawaii, Massachusetts, and the District of Columbia; and 35% or more in 16 states (Alabama, Arkansas, Delaware, Indiana, Iowa, Kansas, Kentucky, Louisiana, Michigan, Mississippi, Ohio, Oklahoma, South Carolina, Tennessee, Texas, and West Virginia).[8] In fact, US obesity and severe obesity prevalence has increased from 1999-2000 to 2017-2018, 30.5% to 42.4% and 4.7% to 9.2%, respectively.[8] Additionally, 19.3% (14.4 million) of all US children and adolescents, aged 2 to 19 years, were obese (BMI ≥ 95th percentile-for-age on the gender-appropriate BMI-for-age Centers for Disease Control and Prevention's [CDC] 2000 growth chart).[7,9] The prevalence of obesity in children varied by age group: 2 to 5 years, 13.4%; 6 to 11 years, 20.3%; and, 12 to 19 years, 21.2%.[7] The consequences of obesity are numerous and include type 2 diabetes mellitus, cardiovascular disease, hypertension, and stroke. Obesity contributes significantly to all-cause mortality and decreased life expectancy.[10]

Because malnutrition is associated with higher morbidity and mortality rates in many settings, an effective nutrition screening program is essential to identify patients at nutrition-related risk, alerting clinicians to perform a comprehensive nutrition assessment to accurately characterize baseline nutrition status, estimate nutrition needs, and develop a patient-specific nutrition care plan. Diligent monitoring of ongoing nutrition status can ensure that nutrition-related goals are being met and improve patient outcomes.

NUTRITION SCREENING

② Nutrition screening is distinct from nutrition assessment; an effective screening process should be designed to identify quickly and consistently those with pre-existing malnutrition or those at risk for malnutrition.[11] It is not practical, expedient, cost-effective, nor clinically warranted to conduct a comprehensive nutrition assessment on every individual; thus, nutrition screening provides a reliable, systematic method to identify persons for whom a detailed nutrition assessment is warranted. A validated nutrition screening tool can be used to detect those who are overweight, obese, malnourished, or at risk for malnutrition; predict their health outcomes based on nutrition-related factors; and identify individuals who would benefit from nutritional intervention.[11,12]

The ideal nutrition screening tool is quick, simple, and noninvasive and can be done by lay and healthcare providers in homes, long-term care facilities, ambulatory care clinics, and hospitals. In 1995, The Joint Commission implemented a standard for accredited healthcare institutions requiring a nutrition screen be completed within 24 hours of inpatient admission on all applicable patients.[13] Because nutrition assessment has been routinely adopted in the United States, this standard was deleted in 2016. Periodic rescreening should occur at regular intervals determined by the institution and the patient population, usually every 3 to 7 days. For outpatients, nutrition screening should occur at the first visit with a new provider and thereafter as warranted by the patient's condition.

Risk factor identification is the foundation of appropriate nutrition screening. Risk factors for malnutrition include recent unintended weight loss; presence and severity of acute and chronic disease states; medications and or other treatments; socioeconomic factors that may result in a decreased nutrient intake; and, altered nutrient absorption, metabolism, or utilization. Risk factors for obesity include a family history of obesity, certain medical diagnoses (eg, polycystic ovary syndrome, Prader-Willi syndrome, Cushing's syndrome), poor dietary habits, inadequate exercise, and some medication therapies. Various rating and classification systems have been proposed to screen for nutrition risk and guide subsequent interventions.[11] In general, checklists of varying complexity are used to quantify a person's food and alcohol consumption habits; ability to buy, prepare, and eat food; weight history; diagnoses; medical and surgical procedures; medication and supplement therapies; and, history of nutrition support (enteral nutrition [EN] or parenteral nutrition [PN]). Although no tool is 100% sensitive and specific for detecting malnutrition, the Mini Nutritional Assessment – Short Form and the Malnutrition Screening Tool (MST) have high sensitivity and specificity.[12] The Mini Nutritional Assessment – Short Form is used extensively in older adults and found to be useful in several care settings.[12] The Nutrition Risk Screening 2002 (NRS 2002) and the Nutrition Risk in the Critically Ill (NUTRIC) may be used as nutrition assessment tools in critically ill adults, but supporting literature is limited.[14–16] Given the drawbacks with use of these tools, a more simple approach is to ask two simple questions: 1) Has there been a recent weight loss of at least 5% to 10%?; and 2) Has there been inadequate food intake for at least 1 to 2 weeks? If the answer to either question is *Yes*, then further assessment is warranted.[11] Nutrition screening for children generally is based on the evaluation of growth parameters against the World Health Organization (WHO; birth to 2 years of age) or CDC (2 to 19 years of age) growth charts,[9,17] the presence of medical conditions known to increase nutrition risk, and recent changes in weight or food intake. Estimates of the prevalence of in-hospital malnutrition for pediatric and adult patients are variable depending on the patient population, disease severity, and the criteria used. According to data from the 2018 Healthcare Cost and Utilization Project, 8.9% of all US nonmaternal, nonneonatal hospital discharges included a coded diagnosis of malnutrition.[18]

In any setting, patients screened to be nutritionally-at-risk should receive a timely comprehensive nutrition assessment to verify nutrition-related risk and to formulate a complete nutrition care plan which includes monitoring parameters to ensure that desired outcomes are met. For patients who are screened to be *nutritionally-at-risk*, a comprehensive nutrition assessment ideally will be completed by a trained professional within 48 to 72 hours. Most nutrition assessments are completed by dietitians or nurses but may be completed by others including pharmacists, physicians, and physician assistants with training in nutrition support.

NUTRITION ASSESSMENT

③ A comprehensive medical, surgical, and dietary history; a nutrition-focused physical examination (NFPE); and anthropometric and laboratory measurements are essential components of a comprehensive nutrition assessment. Goals of nutrition assessment include identification of risk factors associated with malnutrition, including disorders resulting from macro- or micronutrient deficiencies (undernutrition), obesity (overnutrition), or impaired nutrient absorption, metabolism or utilization; determination of the risk of nutrition-related complications; estimation of nutrition needs; and establishment of baseline nutrition parameters against which to measure nutrition therapy outcomes.[11]

Nutrition-Focused History and Physical Examination

The nutrition-focused medical, surgical, and dietary history serves to identify factors that predispose to malnutrition (eg, prematurity, chronic disease, gastrointestinal [GI] dysfunction, alcohol misuse, acute or chronic inflammation [eg, cancer, surgery, trauma]), and overnutrition (eg, poor dietary habits, limited exercise, chronic disease, family history) (Table 164-1). The clinician should clarify any history of weight gain or loss (intended or unintended), anorexia, vomiting, diarrhea, decreased or restrictive food intake, and EN or PN. Any conditions that suggest ongoing inflammation, including fever, hypothermia, tachycardia, or infection should be documented (Table 164-2).[6]

TABLE 164-1

Pertinent Data from a Nutrition-Focused Medical, Surgical, and Dietary History

Nutrition intake and dietary habits
- Anorexia
- Unusual or absent taste
- Diet, including vegetarian, vegan
- Specialized nutrition support (enteral or parenteral nutrition)
- Supplemental vitamin, mineral, or herbal intake
- Food allergies or intolerances

Underlying pathology with nutritional effects
- Chronic infection or inflammatory state
- Cancer
- Endocrine disorders
- Chronic illness (lung disease, cirrhosis, kidney failure)
- Hypermetabolic states (trauma, burns, sepsis)
- Digestive/absorptive disease, nausea, vomiting, diarrhea, constipation
- Hyperlipidemia

End-organ effects
- Weight changes
- Skin or hair changes
- Exercise intolerance or fatigue
- Gastrointestinal tract symptoms (diarrhea, vomiting, constipation)

Gastrointestinal surgery
- Bariatric surgery
- Small bowel or colon resection or diversion
- Gastrectomy

Miscellaneous
- Catabolic medications or therapies (corticosteroids, immunosuppressive agents, radiation, chemotherapy)
- Other medications (diuretics, laxatives, antipsychotics, anabolic steroids)
- Genetics (body habitus of parents, siblings, family)
- Alcohol or drug misuse
- Pregnancy or lactation

TABLE 164-2

Assessment of Inflammation

Laboratory Assessment	Clinical Findings	Acute/Chronic Disease States
Decreased Albumin Transferrin Prealbumin Nitrogen balance Elevated CRP Serum glucose % neutrophils Decreased or increased WBC	Fever Hyperthermia Infection Urinary tract Pneumonia Bacteremia Wound/incision Abscess	Cancer Celiac disease Cystic fibrosis Inflammatory bowel disease Organ failure (ARDS) Pancreatitis Rheumatologic disorders (RA, SLE) Trauma (burns, major surgery, TBI)

ARDS, adult respiratory distress syndrome; CRP, C-reactive protein; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; TBI, traumatic brain injury; WBC, white blood cell count.

The NFPE uses a system-based approach to assess for abnormal nutrition-related clinical and physical findings in each region of the body. Components of the NFPE include: general inspection; vital signs; skin; nails; head/hair; eyes/nose; mouth; neck/chest; abdomen; and, musculoskeletal.[15] The clinician completing a NFPE assesses for muscle and fat loss; fluid status; micronutrient deficiency/toxicity; functional status/hand grip strength; and, for children, mid-arm muscle circumference (MUMC).[19,20] Findings commonly associated with malnutrition (eg, muscle wasting, alopecia, dermatitis, glossitis, cheilosis, jaundice) are noted (Table 164-3).

TABLE 164-3

Nutrition Focused Physical Examination (NFPE) Findings Suggestive of Malnutrition

General Inspection
- Edema
- Cachexia or obesity
- Signs/symptoms of dehydration (poor skin turgor, sunken eyes, orthostasis, dry mucous membranes)
- Muscle wasting or loss of subcutaneous fat

Vital Signs
- Fever
- Tachycardia

Skin
- Thin, shiny, dry, or scaly skin
- Dermatitis, rash
- Decubitus ulcers, poorly healing wounds
- Bruising, petechiae
- Follicular hyperkeratosis
- Pallor, cyanosis, jaundice

Nails
- Spoon shape, clubbing
- Transverse ridging/banding
- Mottled, pale, poor blanching

Head/Hair
- Dry, dull, brittle, sparse, easily pluckable hair
- Corkscrew, coiled, or depigmented hair
- Alopecia
- Scaly, flaky scalp
- Moon face
- Bilateral temporal wasting

Eyes/Nose
- Dull dry appearance to sclerae or inner lids
- Dull milky appearance of cornea
- Bitot's spots[a]
- Icteric sclerae
- Pale conjunctiva
- Cracked red corners of eyes

Mouth
- Pale, red, or bleeding gums
- Dry, cracked, red lips
- Fissures at corners (angular stomatitis)
- Vertical cracks of the lips (cheilosis)
- Magenta or beefy red tongue (glossitis)
- Atrophied papillae
- Excessive dental caries

Neck/Chest
- Enlarged thyroid
- Distended neck veins
- Prominent bony chest, visible ribs (muscle and fat wasting)

Abdomen
- Scaphoid, concave, or protuberant abdomen
- Hepatomegaly, ascites

Musculoskeletal
- Ataxia (poor muscle control)
- Numbness, tingling
- Swollen or painful joints
- Rickets, knock knees, bowleg

[a] Bitot's spots are foamy spots on the surface of the eye.

The Subjective Global Assessment (SGA) and the tool described in the Academy of Nutrition and Dietetics (AND) and the American Society for Parenteral and Enteral Nutrition (ASPEN) consensus statement on the identification and documentation of adult malnutrition are representative examples of a relatively simple, reproducible, cost-effective, bedside approach to nutrition assessment.[1,11] The SGA assesses five aspects of the medical and dietary history: weight change in the previous 6 months, dietary changes, GI symptoms, functional capacity, and disease states known to affect nutrition status. Weight loss of less than 5% of UBW is considered a "small" loss, 5% to 10% loss is "potentially significant," and more than a 10% loss is "definitely significant." Dietary intake is characterized as normal or abnormal, and the duration and degree of abnormal intake are noted. The presence of daily GI symptoms (anorexia, nausea, vomiting, diarrhea) for longer than 2 weeks is significant. Functional capacity assesses the patient's energy level and whether the patient is active or bedridden. Finally, disease state impact on metabolic demands (no, low, moderate, or high stress) is documented. Four physical examination findings are rated as normal, mild, moderate, or severe: loss of subcutaneous fat (triceps and chest), muscle wasting (quadriceps and deltoids), edema (ankle and sacral), and ascites. The patient's nutrition status is then rated as adequately nourished, moderately malnourished or suspected of being malnourished, or severely malnourished. Critics of the SGA find it time-consuming and complex. The AND/ASPEN consensus tool assesses six characteristics: insufficient energy intake, weight loss, loss of muscle mass, loss of subcutaneous fat, localized or generalized fluid accumulation, and diminished functional status measured by hand grip strength. The presence of two or more of these characteristics identifies malnutrition in an adult.

Given variability in diagnostic criteria for malnutrition, the Global Leadership Initiative on Malnutrition (GLIM) was convened to reach global consensus.[3] GLIM established a two-step model that includes malnutrition risk screening of at-risk individuals with a validated tool and assessment for diagnosis and severity grading. Patients who are identified at-risk undergo diagnostic assessment that incorporates phenotypic criteria (nonvolitional weight loss, low BMI, reduced muscle mass) and etiologic criteria (reduced food intake or assimilation, disease burden/inflammatory condition). Malnutrition is diagnosed in patients with at least one phenotypic and one etiologic criterion with further severity grading based on phenotypic metrics.

Anthropometric Measurements

④ Anthropometrics, physical measurements of the size, weight, and proportions of the human body, are important parameters used to assess nutrition status. Common measurements are weight, stature (standing height or recumbent length), waist circumference, and head circumference (occipital frontal circumference) for children younger than 3 years of age. Measurement of limb size, such as skinfold thickness, MUMC, and wrist circumference, may be useful in selected individuals. Accurate measurement of anthropometrics rather than the use of self-reported values is critical for accurate assessment. Measurement can be difficult in injured and critically ill patients but should be conducted as soon as feasible.

Bioelectrical impedance analysis (BIA) is also an anthropometric assessment tool. Body measurements can be compared with normative population standards to identify clinical concerns and may be repeated at various intervals to monitor response to a nutrition care plan. In adults, nutrition-related changes in anthropometric measurements tend to occur slowly; several weeks or more may be required before detectable changes are noted. In infants and young children, changes occur more quickly. Significant acute changes in weight and skinfold thickness usually reflect changes in hydration status, which must be considered when interpreting these parameters.

Weight, Stature, and Head Circumference

Body weight is a nonspecific measure of body cell mass, representing skeletal mass, body fat, and the energy-using component, lean body mass (LBM). Fat-free mass includes skeletal muscle, bone, connective tissue, organs, and water while fat mass includes the subcutaneous fat beneath the skin and the visceral (internal) fat. Change in weight over time, particularly in the absence of edema, ascites, or voluntary losses, is an important indicator of altered LBM. Actual body weight (ABW) interpretation should include consideration of ideal weight-for-height, referred to as ideal body weight (IBW), UBW (typical weight), fluid status, and age (Table 164-4). Both acute and chronic changes in fluid status can affect the ABW; these changes often can be detected by monitoring the patient's daily fluid intake and output. Patients who are dehydrated will have a decreased ABW but not a loss of LBM. Once rehydrated, these patients must be reweighed to establish an appropriate baseline weight for nutrition evaluation. Edema and ascites increase total body water (TBW), thus increasing ABW but not LBM. The ABW of patients with severe edema and ascites should not be used for nutrition assessment, and practitioners often use an estimated "*dry weight*" to account for this TBW increase.

TABLE 164-4

Evaluation of Body Weight and Waist Circumference

Parameter	Interpretation	NHLBI Obesity Classification	Waist Circumference	
ABW compared with IBW				
ABW <69% IBW	Severe malnutrition			
ABW 70%-79% IBW	Moderate malnutrition			
ABW 80%-89% IBW	Mild malnutrition			
ABW 90%-120% IBW	Normal			
ABW >120% IBW	Overweight			
ABW ≥150% IBW	Obese			
ABW ≥200% IBW	Morbidly obese			
ABW compared with UBW				
ABW 85%-95% UBW	Mild malnutrition			
ABW 75%-84% UBW	Moderate malnutrition			
ABW <75% UBW	Severe malnutrition			
BMI (kg/m^2)				
Adults				
<16	Severe malnutrition			
16-16.9	Moderate malnutrition			
17-18.9	Mild malnutrition			
19-24.9	Healthy		Disease risk above BMI-related risk[a]—Waist Circumference	

22-30 (Older adults)	Healthy		Women ≤89 cm (35 in) Men ≤102 cm (40 in)	Women >89 cm (35 in) Men >102 cm (40 in)
25-29.9	Overweight		Increased	High
30-40	Moderate obesity			
30-34.9		I	High	Very high
35-39.9		II	Very high	Very high
>40	Severe or morbid obesity	III	Extremely high	Extremely high
Children				
BMI for age <5th percentile	Underweight			
BMI for age 5th-84th percentile	Healthy			
BMI for age 85th-94th percentile	Overweight			
BMI for age ≥95th percentile	Obese			

[a]Increased risk for Type 2 diabetes mellitus, hypertension, and cardiovascular disease.

NHLBI, National Heart, Lung, and Blood Institute.

The IBW is a population reference standard against which the ABW can be compared. IBW-for-height reference tables are available, and IBW can be calculated using mathematical equations based on sex and height. The most commonly used equations for calculating IBW for adults are the Devine equations where IBW is calculated as follows:[21]

$$\text{Adult men: IBW} = 50\text{ kg} + (2.3 \times \text{inches over 6 feet})$$
$$\text{Adult women: IBW} = 45.5\text{ kg} + (2.3 \times \text{inches over 6 feet})$$

Adult men:IBW=50 kg+(2.3×inches over 6 feet)Adult women: IBW=45.5 kg+(2.3×inches over 6 feet)

Adjusted body weight (AdjBW) has been suggested as a logical means to account for the percentage of the obese weight that is LBM (22% to 38%). For obese adults, use of an AdjBW has been recommended for nutrition-related calculations, as follows:

$$\text{AdjBW} = ([\text{ABW} - \text{IBW}] \times 0.25) + \text{IBW}$$

AdjBW=([ABW−IBW]×0.25)+IBW

However, the use of AdjBW is generally not recommended; its use is not evidence-based because most of the metabolic rate equations were formulated using ABW in a mix of obese and nonobese individuals.[22]

Multiple methods are available for estimating the IBW of children.[23] The Traub equation can be used for a child younger than 18 years of age and 60 inches or shorter:

$$\text{IBW} = ([\text{height(cm)}]^2 \times 1.65)/1{,}000$$

IBW=([height(cm)]2×1.65)/1,000

The McLaren method uses the WHO or CDC growth chart to compare height and weight relative to the child's age. A vertical line is graphed between the child's height-for-age measurement and the corresponding 50th percentile weight-for-age to determine the IBW. This approach becomes less accurate as the child's height deviates from the 50th percentile.[23]

Change in weight over time can be calculated as a percentage of UBW. Use of UBW as a reference point provides a more accurate reflection of clinically significant weight change over time (Table 164-4). The use of UBW avoids the inherent problems with normative tables and documents comparative changes in body weight. However, unless documented in the medical record, determining UBW depends on patient or family recall, which is often inaccurate. All weight changes should be interpreted relative to time because unintentional weight loss, especially rapid weight loss (5% of UBW in 1 month or 10% of UBW in 6 months), increases the risk of nutrition-related poor clinical outcomes.[12]

Stature is determined by both genetics and nutrition. Accurate measurement of stature is critical to appropriate interpretation. In older children and adults, a standing height should be obtained. If a standing height cannot be measured using a wall-mounted stadiometer, recumbent length, knee height, and arm spam have been used. Each of these methods yields different results.[24] In infants and young children who are unable to stand, a recumbent length is measured using a *length board* which requires two people to obtain an accurate measurement.

Demispan is determined in a seated patient by measuring the distance from the sternal notch to the web between the middle and ring fingers along a horizontally outstretched arm with the wrist in neutral rotation and zero extension or flexion. Demispan may more accurately assess stature in elderly adults, especially those with kyphosis or vertebral collapse. After the demispan is measured, height is estimated using the following equations:[25]

$$\text{Women: Height (cm)} = (1.35 \times \text{demispan [cm]}) + 60.1$$
$$\text{Men: Height (cm)} = (1.4 \times \text{demispan [cm]}) + 57.8$$

Women:Height (cm)=(1.35×demispan [cm])+60.1Men:Height (cm)=(1.4×demispan [cm])+57.8

Knee height may also be used to estimate stature and is helpful in patients with limb contractures, such as patients with cerebral palsy and the elderly. Knee height is measured from just under the heel to the anterior surface of the thigh just proximal to the patella. Using the average of two measurements rounded to the nearest 0.1 cm, height can be estimated using the following equations:[12]

$$\text{Women}: \text{Height(cm)} = [1.83 \times \text{knee height(cm)}] - [0.24 \times \text{age(yr)}] + 84.8$$

$$\text{Men}: \text{Height(cm)} = [2.02 \times \text{knee height(cm)}] - [0.04 \times \text{age(yr)}] + 64.9$$

Women:Height(cm)=[1.83×knee height(cm)]−[0.24×age(yr)]+84.8Men:Height(cm)=[2.02×knee height(cm)]−[0.04×age(yr)]+64.9TFN(mg/dL)=

$$TFN(mg/dL) = (total\ iron - binding\ capacity[mcg/dL] \times 0.8) - 43$$

(total iron−binding capacity[mcg/dL]×0.8)−43

Appropriate growth is predictable and the best indicator of adequate nutrition in a child. At each medical encounter, weight, stature, head circumference (until 3 years), and BMI (after 2 years) should be plotted on the WHO (younger than 2 years) or CDC gender- and age-specific growth curves.[9,17] The CDC charts were revised in 2000 from US data only and indicate how US children grow. The WHO charts developed in 2006 are preferred in those younger than 2 years because they include data from infants from six industrialized countries including the United States who were predominantly breastfed for the first 4 months of life and who were receiving some breast milk at 12 months, conditions felt to ensure optimal growth.[17] Specialized charts are also available for assessment of growth of premature infants.[26,27] For premature infants with corrected postnatal age of 40 weeks or more, the WHO growth charts can be used; however, weight-for-age, length-for-age, and head circumference-for-age should be plotted according to corrected postnatal age until 2 years, 1.5 to 3 years, and 3 years of age, respectively.

Recommended intervals between measurements in young children are weight, 7 days; length, 4 weeks; height, 8 weeks; and head circumference, 7 days in infants and 4 weeks in children until 3 years of age. Daily weight fluctuations can occur with changes in fluid status. Growth velocity can be used to assess growth at intervals too close to plot accurately on a growth chart (Table 164-5). In newborns, average weight gain is 10 to 20 g/kg/day (24-35 g/day in term infants; 10-25 g/day in preterm infants depending on gestational age). The rate of weight gain declines considerably after 3 months of age; children 6 to 10 years of age gain about 2 to 3 kg/yr. The adolescent “growth spurt” typically begins at 9 to 10 years in girls and 11 to 12 years in boys. During the 11 to 13 year-old-interval of maximum growth in height, girls will gain about 10 kg (22 lb) while boys gain 15.5 kg (33 lb). Length increases rapidly in infancy (see Table 164-5). In children 6 to 10 years of age, height increases by 2 to 3 in/yr (approximately 5-7.5 cm/yr) and continues until about 16 to 18 years of age in girls and 18 to 20 years of age in boys. Head growth (measured by head circumference), usually 0.5 cm/wk (0.2 in/wk) during the first year of life, can be compromised during periods of critical illness or malnutrition. Rapid head growth, at a rate faster than expected, suggests hydrocephalus which may be benign but must be further evaluated.

TABLE 164-5

Expected Growth Velocities in Term Infants and Children

Age	Weight (g/day)	Height (cm/mo)[a]
0-3 mo	24-35	2.8-3.4
4-6 mo	15-21	1.7-2.4
7-12 mo	10-13	1.3-1.6
1-3 yr	5-9	0.6-1
4-6 yr	5-6	0.5-0.6
7-10 yr	7-11	0.4-0.5

Example of growth assessment
Age: 2 mo; weight: 3.2 kg; weight at 1 mo of age, 3.1 kg; time since last weight was obtained: 30 days.
Growth velocity = ([3.2 kg–3.1 kg] × 1,000 g/kg)/30 days = 3.3 g/day.
Interpretation: suboptimal growth; comprehensive nutrition assessment needed.

[a] Growth velocity of 1 cm/mo is equivalent to 0.4 in/mo.

In the International Classification of Disease-10 (ICD-10), failure-to-thrive (growth faltering) in a child is defined as *lack of expected normal physical growth*, *failure to gain weight*, or *lack of growth*. Not all children with low weight have failure-to-thrive, but it has been defined as weight-for-age, length-for-age, BMI-for-age, or weight velocity below the 2nd percentile or a weight deceleration crossing two or more major percentiles (major percentiles are defined as 97th, 95th, 90th, 75th, 50th, 25th, 10th, 5th, and 3rd), or if an infant is not gaining the expected daily weight.[28] In children, a significant weight loss is defined as: greater than 2% in 1 week; greater than 5% in 1 month; greater than 7.5% in 3 months; and, greater than 10% in 6 months. Growth faltering is best defined by using z-scores for weight-for-length, BMI-for-age, or length- or height-for age: a z-score of -1 indicates mild malnutrition; -2 moderate malnutrition; and, -3 severe malnutrition.[2] Weight-for-height evaluation is age independent and helps differentiate a stunted child (chronic malnutrition) from a wasted child (acute malnutrition). Short stature can be associated with chronic undernutrition, but short stature in the absence of poor weight gain suggests another etiology, such as growth hormone deficiency or constitutional growth delay.[29]

Body Mass Index

BMI can be calculated as either body weight in kilograms divided by height in meters squared (kg/m^2) or body weight in pounds multiplied by 703 divided by height in inches squared (lb/in^2). The assessment of BMI is the first step but not the sole criterion to judge potential health risk.[30] A BMI of 25 kg/m^2 or higher is a risk factor for premature death and disability. Health risks increase with increasing BMI; however, individual variation, especially in very muscular persons, can lead to erroneous nutrition status classification when BMI alone is used. Thus, BMI must be interpreted based on characteristics such as sex, frame size, race/ethnicity, and age. For example, at the same BMI, a woman tends to have more body fat than a man, and an older adult will have more body fat than a younger one.

The National Institutes of Health obesity expert panel report classifies a BMI between 18.5 and 24.9 kg/m^2 as a healthy or normal weight, between 25 kg/m^2 and 29.9 kg/m^2 as overweight, between 30 kg/m^2 and 39.9 kg/m^2 as obese; and, 40 kg/m^2 or higher as extreme obesity (see Table 164-4).[31] These BMI classifications may not be appropriate for adults older than 60 to 65 years. The Centers for Medicaid and Medicare Services defines normal BMI for adults older than 65 years to be between 23 kg/m^2 and 30 kg/m^2; the National Screening Initiative defined normal BMI for this age as 22 to 27 kg/m^2. The NIH classifies a BMI of less than 18.5 kg/m^2 as undernutrition, but this relationship is not as well established.[31] BMI values below 18.5 kg/m^2 have been associated with higher mortality rates in patients with cancer.[32] Children 2 years of age and older whose BMI is at or above the 85th percentile or at or above the 95th percentile on the age- and gender-specific CDC BMI chart are classified as overweight and obese, respectively.[9,17] Use of these charts at each medical encounter helps to heighten awareness of children whose BMI and family history put them at risk for adult obesity and its associated complications.

Waist Circumference

Body fat distribution is associated with health risk. Waist circumference is a simple measurement used to assess abdominal (visceral) fat. Waist circumference is determined by measuring the distance around the smallest area below the rib cage and the top of the iliac crest. Extra weight around the waist rather than peripheral (subcutaneous) fat confers a greater health risk than extra weight around the hips and thighs. The larger the waist circumference, the greater the risk of obesity-related complications, especially diabetes mellitus, cardiovascular disease, and all-cause mortality.[30,33] Men and women are considered to have abdominal obesity and at increased risk (beyond their BMI-related risk) when the waist circumference is greater than 40 inches (102 cm) and greater than 35 inches (89 cm), respectively (Table 164-4). Children have abdominal obesity if the waist circumference is at or above the 90th percentile according to CDC age- and sex-specific standards.[34]

Waist-to-Hip and Waist-to-Height Ratios

The waist-to-hip ratio is determined by dividing the waist circumference by the hip circumference (maximal posterior extension of the buttocks). In adults, a waist-to-hip ratio of greater than 0.9 in men and 0.85 in women is considered an independent risk factor for adverse health consequences.[33] Waist-to-height ratio (both measured in centimeters) has been used to evaluate children at risk for the metabolic syndrome because, unlike waist circumference, it is independent of age and sex. A child (aged 6 to 18 years) with a waist-to-height ratio of more than 0.5 is considered to have abdominal obesity and at risk for developing the metabolic syndrome. This cutoff may overestimate abdominal obesity in younger children (aged 2 to 5 years).[34]

Skinfold Thickness and Mid-Arm Muscle Circumference

More than 50% of the body's fat is subcutaneous; thus, changes in subcutaneous fat reflect changes in total body fat. Skinfold thickness measurement provides an estimate of subcutaneous fat, and MUMC, which is calculated using the skinfold thickness and mid-arm circumference, estimates skeletal muscle mass. Although simple and noninvasive, these anthropometric measurements are used most commonly in population analysis and long-term monitoring of individuals. Triceps skinfold thickness measurement is used most often, but reference standards also exist for subscapular and suprailiac measurements.[35] Consistent technique in the use of pressure-regulated calipers is essential for reproducibility and reliability in measuring skinfold thickness. Published standards do not account for variation in bone size, muscle mass, hydration, or skin compressibility, and they do not consider obesity, ethnicity, illness, and increased age. Results should be interpreted cautiously as these parameters change slowly in adults, often requiring weeks before significant alterations from baseline can be detected. These parameters will change more rapidly in young children.

Bioelectrical Impedance

BIA is a portable, simple, quick, noninvasive, and relatively inexpensive technique used to measure body composition.[36,37] When a weak, alternating electric current is applied to two appendages (wrist and ankle or both feet), impedance (resistance) to flow is measured as it passes through the body. Different body tissues have varying amounts of water and will conduct the electrical current differently. Water and electrolyte-rich tissues such as blood and muscle are highly conductive, but fat and bone are poor conductors. Assessment of LBM, TBW, and water distribution can be determined with BIA. Increased TBW decreases impedance; thus, it is important to evaluate hydration status when performing BIA. Other potential limitations of BIA include variability with electrolyte imbalance and interference by large fat masses, environment, ethnicity, menstrual cycle phase, and underlying medical conditions.[37] Although BIA equations have high validity when used in the population in which they were developed (mostly young healthy adults), BIA calculations are subject to considerable errors if applied to other populations or when conditions are not identical (eg, electrode placement).[37] The use of BIA in clinical practice may be limited by the lack of reference standards that reflect variations in individual age, body size, and clinical conditions.[36] Due to the proprietary nature of manufacture-specific BIA regression models and inability to compare studies using different devices, current guidelines do not provide recommendations regarding the use of BIA in clinical practice.[38]

OTHER NUTRITION ASSESSMENT TOOLS

Functional status is dependent on nutrition, but the specific tools to assess it are not well defined. Muscle function is an end-organ response; thus, diminished skeletal muscle function can be a useful indicator of malnutrition. Muscle function may also recover more quickly in response to adequate nutrition support than anthropometric measurements. Simple functional assessments include the ability to perform activities of daily living, participate in physical and occupational therapy, and wean from the ventilator. Hand-grip strength (forearm muscle dynamometry), respiratory muscle strength, and muscle response to electrical stimulation also have been used. Measuring hand-grip strength is part of a NFPE and is a relatively simple, noninvasive, and inexpensive procedure that correlates well with patient outcome.[39–41] Normative standards supplied by the manufacturer of the specific dynamometer must be used for assessment. Hand grip strength is an indirect measurement of LBM making it a good parameter for assessment of undernutrition. However, some conditions will limit hand grip strength, such as rheumatoid arthritis, stroke, neuromuscular disease, dementia, and heavy sedation. Ulnar nerve stimulation causes measurable muscle contraction and is used in most intensive care units to monitor neuromuscular blockade. In malnourished patients, increased fatigue and a slowed muscle relaxation rate are noted, and these indices may return to normal with refeeding.

Other methods used to determine body composition include bioimpedance spectroscopy, dual energy x-ray absorptiometry (DXA), quantitative computed tomography (CT), air displacement plethysmography (BodPod®), three-dimensional photonic scanning, quantitative magnetic resonance imaging (MRI), ultrasonography, and positron emission tomography.[14,37,38,42] These methods are often complex and expensive to perform. DXA, best known for its use in measuring bone density, is a promising method for routine clinical practice because it can quantify mineral, fat, and LBM compartments and is available in most hospitals and many outpatient facilities. Current guidelines recommend the use of DXA for assessing fat mass in patients with a variety of disease states, but the validity for lean mass assessment is unknown.[38] A central body DXA scanner requires a fair amount of space, and the cost depends on the scanner's complexity. Portable (or peripheral) DXA devices can be used to measure bone density in peripheral bones, such as the wrist, fingers, or heel, and have also been used to assess subcutaneous fat. Portable DXA scanners are much less expensive than central scanners and can be used in community screenings. Further research is needed to determine how DXA can be used clinically in nutrition assessment. MRI and CT can measure subcutaneous, intra-abdominal, and regional fat distribution and thus also have the potential to be useful clinically. Ultrasound uses high-frequency sound waves to image soft tissue structures in an inexpensive and noninvasive manner. Current guidelines do not recommend ultrasound to assess body composition due to the lack of data evidence for supporting its validity in clinical practice.[38]

Laboratory Assessment

⑤ Laboratory assessment of nutrition status must be interpreted in the context of clinical status and acute and chronic inflammation. Biochemically, serum visceral proteins (ALB, TFN, and prealbumin [also known as transthyretin]) have traditionally been used to assess LBM. C-reactive protein (CRP) can be useful as a marker of inflammation.

Serum Visceral Proteins

Visceral proteins synthesized by the liver have historically been considered useful parameters for nutrition assessment, but newer literature challenges this premise.[43] It is assumed that in undernutrition states, a low serum protein concentration reflects diminished hepatic protein synthetic mass and indirectly reflects the functional protein mass of other organs (heart, lung, kidney, and intestines). However, visceral proteins are not valid proxy measures of total body mass.[43] Many factors other than nutrition can affect the serum concentrations of these proteins including age; abnormal kidney (nephrotic syndrome), GI tract (protein-losing enteropathy) or skin (burns) losses; hydration (dehydration results in hemoconcentration, overhydration in hemodilution); liver function (synthesis); and metabolic stress and inflammation (chronic disease, sepsis, trauma, surgery, infection). Thus, visceral protein concentrations must be interpreted relative to the individual's overall clinical condition and inflammatory state (Table 164-6).

TABLE 164-6

Serum Proteins Associated with Nutrition Risk

Serum Protein	Half-Life (Days)	Function	Factors Resulting in Increased Values	Factors Resulting in Decreased Values
Albumin	18-20	Maintains plasma oncotic pressure; transports small molecules	Dehydration, anabolic steroids, insulin, infection	Fluid overload; edema; kidney dysfunction; nephrotic syndrome; poor dietary intake; impaired digestion; burns; heart failure; cirrhosis; thyroid, adrenal, or pituitary hormones; trauma; sepsis
Transferrin	8-9	Binds Fe in plasma; transports Fe to bone	Fe deficiency, pregnancy, hypoxia, chronic blood loss, estrogens	Chronic infection, cirrhosis, burns, enteropathies, nephrotic syndrome, cortisone, testosterone
Prealbumin (transthyretin)	2-3	Binds T3 and, to a lesser extent, T4; retinol-binding protein carrier	Impaired kidney function	Cirrhosis, hepatitis, stress, surgery, inflammation, hyperthyroidism, cystic fibrosis, burns, zinc deficiency

T3, triiodothyronine; T4, thyroxine.

The significant influence of inflammation on visceral protein concentrations is now well established; thus, these *negative acute phase reactants* may be considered to reflect the extent of physiologic stress or inflammation rather than the presence of undernutrition (Table 164-3).[43,44] During severe acute stress (eg, trauma, burns, sepsis), these proteins are decreased because the resultant increased vascular permeability can lead to dramatic fluid shifts and the reprioritizing of liver protein synthesis increases the production of acute-phase reactants such as CRP, ferritin, fibrinogen, and haptoglobin.[11,44] CRP is a true acute-phase protein rising within 10 hours after major surgery or acute sepsis; it can be used to assess the degree of inflammation present.[44] If CRP is elevated, then inflammation is likely contributing to decreased visceral protein concentrations making visceral proteins inflammatory markers associated with nutrition risk rather than markers of malnutrition or protein and energy intake inadequacy.[43] The role of visceral protein monitoring in nutrition support remains unclear; however, normalizing values may indicate resolving stress and inflammation, decreased nutrition risk, shift to anabolism, and/or decreasing nutritional requirements.[43] Thus, assessing individual patient trends, not comparison to normative standards, may be useful in monitoring recovery.

ALB is the most abundant serum protein and is critical for the maintenance of colloid oncotic pressure and binding and transport of numerous hormones, anions, medications, and fatty acids. As an insensitive index of protein malnutrition, albumin is not a component of currently accepted definitions for malnutrition.[43] Factors that lead to albumin's insensitivity include the large amount normally in the body (4-5 g/kg of body weight), extensive distribution in the extravascular compartment (60%), and long half-life (18-20 days). As discussed, ALB is a negative acute-phase reactant, and serum concentrations decrease with inflammation, infection, trauma, stress, and burns. Serum ALB concentrations less than 2.5 g/dL (25 g/L) can be expected to exacerbate ascites and peripheral, pulmonary, and GI mucosal edema because of decreased colloid oncotic pressure. Hypoalbuminemia also affects the interpretation of serum concentrations of calcium and highly protein bound medications (eg, phenytoin, valproic acid).

Transferrin is a glycoprotein that binds and transports ferric iron to the liver and reticuloendothelial system for storage. TFN is also a negative acute-phase reactant, and its concentration is decreased in the presence of critical illness and inflammation.[12] Because it has a shorter half-life (8-9 days) and there is less of it in the body (less than 100 mg/kg of body weight), TFN concentrations decreases in response to various factors before the serum ALB concentration. If a direct measure of serum TFN is not available, TFN concentration can be estimated indirectly from measurement of total iron-binding capacity, as follows:

$$\text{TFN(mg/dL)} = (\text{total iron}-\text{binding capacity[mcg/dL]} \times 0.8) - 43$$

Alternatively, TFN (mg/dL) = 0.7 × total iron-binding capacity (mcg/dL) and TFN (g/L) = 0.039 × total iron-binding capacity (μmol/L). Iron stores affect serum TFN concentrations: in iron deficiency, hepatic TFN synthesis is increased, resulting in increased serum TFN concentrations.

Prealbumin (transthyretin) is the transport protein for thyroxine and a carrier for retinol-binding protein. While prealbumin was historically used to monitor the short-term, acute effects of nutrition support or deficits, it is now recognized as an inflammatory marker that may be associated with risk of developing malnutrition or poor clinical outcomes.[43] Prealbumin stores are low (10 mg/kg of body weight), and it has a very short half-life (2-3 days); thus, the serum prealbumin concentration will decrease rapidly with severe metabolic stress (trauma, burns, sepsis). As with ALB and TFN, prealbumin synthesis is decreased in liver disease. Prealbumin is renally excreted, so falsely elevated prealbumin concentrations may be seen in patients with kidney dysfunction.

Nitrogen Balance Study

Nitrogen is found only in protein and at a relatively constant ratio of 1 g nitrogen per 6.25 g of protein. This ratio may vary somewhat for EN and PN formulations, depending on the biologic value of the protein source. The adequacy of protein intake can be assessed clinically by a nitrogen balance study—measuring urinary nitrogen excretion and comparing it with nitrogen intake. Nitrogen balance indirectly reflects protein utilization and/or the protein catabolic rate. As the stress level increases, a concomitant increase in protein catabolism (hypercatabolism) results in an increase in urinary nitrogen excretion. The amount of urine urea nitrogen (UUN) measured in a 24-hour urine collection in healthy individuals, accounts for 80% to 90% of the total urine nitrogen (TUN) excreted. Nitrogen output (g/day) can be approximated as 24-hour UUN + 4, where 4 is a factor representing usual skin, fecal, and respiratory nitrogen losses.[12] Alternatively, nitrogen output can be estimated using the equation: 24-hour UUN + 2 + 20% of urinary urea losses.[45] At higher UUN values (30 g nitrogen or more), then the use of a factor of + 6 may yield a more accurate measure of nitrogen output.[46] Alternatively, if available, TUN can be measured and may be more accurate, especially in critically ill patients who excrete more nitrogen-containing substances such as 3-methylhistidine. If TUN is used, then the best estimate of nitrogen output is TUN + 1.05, where 1.05 is the average extraurinary nitrogen losses.[46] In patients with decreased kidney function, in which case neither UUN nor TUN accurately represents net protein degradation, nitrogen output can be approximated with equations based on urea nitrogen appearance.[47]

Immune Function Tests

Nutrition status affects immune function either directly, via actions on the lymphoid system, or indirectly by altering cellular metabolism or organs that are involved with immune system regulation. Immune function tests most often used in nutrition assessment are the total lymphocyte count and delayed cutaneous hypersensitivity (DCH) reactions. Both tests are simple, readily available, and inexpensive. A lack of specificity, however, limits the usefulness of these tests as nutrition status markers.

Total lymphocyte count reflects the number of circulating T and B lymphocytes. Tissues that generate T cells are very sensitive to malnutrition, undergoing involution resulting in decreased T-cell production and eventually lymphocytopenia. A total lymphocyte count less than 1200 cells/mm^3 (1.2 × 10^9 cells/L) is a nonspecific marker for nutrition depletion.[12] Total lymphocyte count is reduced in the presence of infection (eg, human immunodeficiency virus [HIV], other viruses, tuberculosis), immunosuppressive drugs (eg, corticosteroids, cyclosporine, tacrolimus, sirolimus, chemotherapy, antilymphocyte globulin), leukemia, and lymphoma.

DCH is commonly assessed using recall antigens to which the patient was likely previously sensitized, such as mumps and *Candida albicans*. Although not specific for nutrition status, anergy is associated with severe malnutrition, and response can be restored with nutrition repletion.[12] Other immune function tests used in nutrition research include lymphocyte surface antigens (eg, CD4, CD8, CD4:CD8 ratio), T-lymphocyte responsiveness, and various serum interleukin concentrations. Factors affecting DCH include fever, viral illness, recent live-virus vaccination, critical illness, irradiation, immunosuppressive drugs, diabetes mellitus, HIV, cancer, and surgery. Nutrients such as arginine, omega-3 fatty acids, and nucleic acids given in pharmacologic doses may improve immune function. Monitoring efficacy of a nutrition care plan that includes these potentially immune-modulating nutrients may include these immune function assessments.

NUTRIENT DEFICIENCIES AND TOXICITIES

⑥ Macronutrient or micronutrient deficiencies or toxicities or risk factors for these deficiencies or toxicities may be identified by a comprehensive nutrition assessment. A comprehensive nutrition assessment should include an evaluation for possible trace element, vitamin, or essential fatty acid deficiencies (EFAD) or toxicities. Because of their key role in metabolic processes (coenzymes and cofactors), a deficiency of any of these nutrients may result in altered metabolism and cell dysfunction. An accurate history to identify symptoms and risk factors for a specific nutrient deficiency or toxicity is critical. A NFPE and biochemical assessment to confirm a suspected deficiency or toxicity should be done in all nutritionally-at-risk patients. Ideally, biochemical assessment would be based on the nutrient's function (eg, metalloenzyme activity) rather than simply measuring the serum concentration. Unfortunately, few practical methods to assess micronutrient function are available; thus, the serum concentration is most often measured (Table 164-7).

TABLE 164-7

Assessment of Trace Element Status

Trace Element	Signs of Deficiency	Signs of Toxicity	Factors Associated with Altered Plasma Concentrations	Monitoring
Chromium	Impaired glucose/protein utilization, peripheral neuropathy, weight loss, increased LDL-C, increased free fatty acid concentrations	Industrial exposure: skin or nasal septum lesions, allergic dermatitis, increased incidence of lung cancer	**Decreased**: long-term inadequate intake **Increased**: kidney failure	Serum glucose, plasma chromium (unreliable)
Copper	Menkes' syndrome: progressive mental deterioration, vomiting, diarrhea, protein-losing enteropathy, hypopigmentation, bone and hair changes Deficiency: neutropenia, hypochromic anemia, pallor, dermatitis, neurological dysfunction, osteoporosis, myopathy, thrombocytopenia, decreased bone mineralization (children)	Wilson's disease: cirrhosis, Kayser-Fleischer rings[a], kidney dysfunction, neurologic or psychiatric symptoms (tremors, slow speech, inappropriate behavior, personality changes) Mild chronic toxicity: fatigue, anemia, thrombocytopenia Acute toxicity: nausea, vomiting, diarrhea	**Decreased**: high zinc, iron, or vitamin C intake; corticosteroid use **Increased**: infection, rheumatoid arthritis, pregnancy, oral contraceptives, decreased biliary excretion	Serum copper and ceruloplasmin with CRP[b], CBC
Iodine	Hypothyroid goiter, neuromuscular impairment, deaf-mutism, increased embryonic and postnatal mortality, cognitive impairment, impaired fertility, congenital hypothyroidism (severe cases)	Thyrotoxicosis: nodular goiter, weight loss, tachycardia, muscle weakness, warm skin	**Decreased**: long-term inadequate intake	Serum T3,T4,TSH
Iron	Microcytic, hypochromic anemia (weakness, pallor, fatigue), glossitis, headache, dysphasia, nail changes, gastric atrophy, paresthesia, decreased cognitive function	Cirrhosis, cardiomyopathy, pancreatic damage, skin pigmentation changes	**Increased**: blood transfusion **Decreased**: blood loss; long-term iron-free PN	Serum ferritin[c], iron, percent iron saturation, iron binding capacity; CBC
Manganese	Nausea; vomiting; dermatitis; hair color changes; hypocholesterolemia; growth retardation; defective carbohydrate, lipid, and protein metabolism	Parkinsonian-like symptoms, hyperirritability, hallucinations, libido disturbances, ataxia, mental confusion, lack of attention, memory loss, weakness, seizures, facial nerve abnormalities, headache, dizziness, dystonia, peripheral neuropathy	**Increased**: decreased biliary excretion, high iron or vitamin C intake	Whole blood manganese, brain MRI
Molybdenum	Tachycardia, tachypnea, altered mental status, visual changes, headache, nausea, vomiting	Gout-like syndrome, increased urinary copper	**Decreased**: low birth weight, excessive GI losses	Urinary hypoxanthine, xanthine, and sulfite oxidase
Selenium	Muscle weakness or pain, cardiomyopathy, skin and hair pigmentation changes, macrocytosis, alopecia and growth retardation in infants	Nausea, vomiting, hair or nail loss, tooth decay, skin lesions, irritability, fatigue, peripheral neuropathy	**Decreased**: malignancy, liver failure, pregnancy, stress, infection **Increased**:	Plasma, serum, or whole blood selenium, RBC glutathione

			reticuloendothelial-neoplasia	peroxidase; CBC
Zinc	Dermatitis (scaly, hyperpigmented skin lesions), stomatitis, glossitis, perioral and periungual ulceration, altered taste and smell, alopecia, diarrhea, apathy, depression, growth retardation, impaired wound healing, anorexia, confusion, immunosuppression, delayed sexual maturation, hypogonadism (decreased sperm count and function)	Acute: diarrhea, vomiting, nausea, dizziness, garlic-smelling breath; death with large IV doses Chronic: immunosuppression, decreased HDL-C, copper deficiency	**Decreased**: infection, burns, stress, hypoalbuminemia, corticosteroids, pregnancy, inflammation **Increased**: tissue injury, hemolysis, contaminated collection tube	Plasma or serum zinc with albumin and CRP, stool or ostomy output, serum copper

CBC, complete blood count; CRP, C-reactive protein; GI, gastrointestinal; HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; MRI, magnetic resonance imaging; PN, parenteral nutrition; RBC, red blood cell; RQ, respiratory quotient; TSH, thyroid stimulating hormone.

[a] Kayser-Fleischer rings are dark rings that appear to encircle the iris of the eye.

[b] If CRP > 4 mg/dL (40 mg/L), serum copper concentration will be falsely elevated. Ceruloplasmin increased with inflammation, pregnancy, liver disease, malignancy, and myocardial infarction.

[c] If ferritin low, iron deficiency; if high, inflammation.

Trace Elements

Trace elements considered essential in humans (at least one important role and a range of intakes within which homeostasis is maintained) are iron, zinc, selenium, copper, chromium, manganese, molybdenum, and iodine. A complete discussion of each of these elements is beyond the scope of this chapter.[48–52] Each trace element is involved in a variety of biologic functions and is necessary for normal metabolism, acting as a coenzyme or in other roles in hormonal metabolism or erythropoiesis. Toxicities can occur with excess intake of some trace elements. With the current interest in complementary medicine, clinicians must ask patients about their use of all dietary supplements.

Iron

Iron is the most abundant trace element and is an important component of hemoglobin, myoglobin, and cytochrome enzymes; it is also involved in oxygen transport and cellular energy production. Patients with iron-deficiency anemia typically present with fatigue, weakness, and pallor. Inadequate iron intake, malabsorption, and chronic blood loss are the principal causes of iron-deficiency anemia. Iron toxicity (overload) with possible organ damage can occur when chronic iron intake exceeds requirements, such as in patients receiving multiple blood transfusions over an extended period (1 unit of packed red blood cells provides 200-250 mg elemental iron). Iron deficiency or overload is confirmed by assessment of iron stores, as reflected indirectly by measurement of hemoglobin, serum iron, total iron-binding capacity, and serum ferritin or directly by bone marrow staining or liver biopsy. Direct methods are most accurate but invasive and rarely necessary. Because indirect parameters such as ferritin are altered by acute or chronic inflammation independent of iron stores, concomitant illness must be considered in their interpretation. As with visceral protein assessment, CRP measurement simultaneously with iron assessments will help to determine the degree to which inflammation influences these parameters.[50]

Zinc

Zinc, the second-most abundant trace element, is a cofactor in many enzymatic reactions involved in protein, fat, and carbohydrate metabolism and is involved in the regulation of gene expression, immunity, growth, wound healing, and liver regeneration.[49,50,53] Most of the body's zinc (85%) is found in muscle and bone; less than 1% is found in the serum. Zinc is eliminated through the urine and the GI tract. Zinc deficiency develops with decreased intake or absorption, increased loss, or increased demand. Risk factors for zinc deficiency include bariatric surgery, anorexia/bulimia, alcohol misuse, excessive fluid losses (bile, intestinal, urine), and increased metabolic demands (sepsis, burns).[53] Urinary zinc losses are increased by thiazide diuretics, angiotensin converting enzyme inhibitors, angiotensin receptor blockers, and hemofiltration.[51] Zinc deficiency can develop in 14 days to 3 months with insufficient intake and is characterized by skin lesions (acrodermatitis enteropathica), a moist eczematous dermatitis that is most apparent in the nasolabial folds and around orifices, and other symptoms (Table 164-7).[49] Recovery is rapid with zinc supplementation; severe dermatitis can improve in as little as 4 to 5 days. Zinc deficiency can be documented by the presence of low serum zinc concentrations. However, serum zinc concentrations decrease during acute stress states and generally remain depressed until the stress resolves. Hair zinc analysis and urinary zinc excretion can be used as biomarkers of zinc status.[53] Excess zinc intake is eliminated by the kidneys and GI tract; thus, zinc toxicity is uncommon except in overdoses or with excessive, prolonged parenteral supplementation.

Selenium

Selenium is not an antioxidant itself but an integral part of selenoproteins. There are 25 genes coding for these selenoproteins, about half of which have a defined metabolic function.

Important selenoproteins include selenoprotein P (antioxidant activity), glutathione peroxidase (antioxidant activity), iodothyronine deiodinase (thyroid hormone regulation), thioredoxin reductase (vitamin C), selenoprotein V (spermatogenesis), and selenoprotein S (inflammation, immune response).[50,54] A key metabolic function of selenium is its role in the enzymatic cofactor selenocysteine, the 21st proteinogenic amino acid.[54] Selenoprotein P is the major (60%) circulating form of selenium in serum.

Prematurity, critical illness, burns, chronic GI losses, and long-term selenium-free PN are associated with low serum selenium concentrations and decreased glutathione peroxidase activity.[49] The clinical significance of reduced serum selenium concentrations is unclear, but low selenium concentrations may increase susceptibility to physiologic stressors. Low serum selenium concentrations in critically ill patients correlate with low triiodothyronine (T_3) concentrations.[55] Serum selenium concentrations reflect acute distribution between tissues rather than selenium stores. Selenium deficiency is associated with muscle pain, wasting, and weakness (see Table 164-7), but severe biochemical deficiency is not always accompanied by these symptoms. Statins inhibit 3-hydroxy-3-methylglutaryl coenzyme A reductase and can induce myopathy by interfering with synthesis of selenoproteins.[50] Fatal cardiomyopathy may occur. Although critically ill patients may require higher selenium intakes than normal, optimal intake is unknown; current recommendations range from 20 to 1,000 mcg/day.[55]

Serum, erythrocyte, and whole-blood selenium; serum selenoprotein P; and serum, platelet, and whole-blood glutathione peroxidase activity respond to changes in selenium intake, but the response is heterogeneous.[56] Decreased serum selenium concentrations may indicate selenium deficiency, but reductions have also been observed in patients with malignancies, liver failure, pregnancy, alcohol misuse, and HIV; in patients receiving statins or corticosteroids; and in patients who smoke. Selenium toxicity (selenosis) generally occurs only in those with long-term exposure to foods grown in selenium-rich soil (eg, US Great Plains area) but may occur when intake exceeds 200 mcg/day or 5 mcg/kg/day for prolonged periods.[50] Selenium toxicity results in hair and nail brittleness and loss, GI disturbance, skin rash, garlic breath odor, fatigue, irritability, nervous system abnormalities, and has been linked to type 2 diabetes mellitus.[54]

Copper

Copper is a cofactor in oxidative enzymes vital to the function of hematopoietic, vascular, and skeletal tissue, as well as structure and function of the nervous system.[47,48,57] It is a component of ceruloplasmin and key metalloenzymes involved in iron and manganese metabolism (ceruloplasmin), electron transfer and oxidation-reduction reactions (cytochrome c oxidase), connective tissue and collagen cross-linking (lysyl oxidase), dopamine conversion to norepinephrine (dopamine monooxygenase), free radical scavenging (superoxide dismutase), and many others.[49,50] Copper is absorbed in the duodenum and excreted through the bile bound to bile salts. Most copper (67%) is found in bone and muscle, and 60% to 95% of serum copper is bound to ceruloplasmin.[58] Signs and symptoms of copper deficiency are listed in Table 164-7 and include anemia, neutropenia, thrombocytopenia, and neurologic dysfunction. In severe cases, such as in Menkes' syndrome, copper deficiency is further manifested as hypothermia, hair and skin depigmentation, progressive mental deterioration, and growth retardation. Factors predisposing to copper deficiency include generalized malabsorption, protein-losing enteropathy, nephrotic syndrome, prematurity, and copper-free PN.[57–59] Long-term PN supplemented with copper may increase the risk of copper toxicity in patients who develop cholestasis; however, copper deficiency has been reported with copper-free PN after copper removal from the PN solution due to a rising direct bilirubin concentration (cholestasis).[58] Patients undergoing bariatric surgery are at risk for copper deficiency as early as 2 months after surgery. Typically 1 to 3 weeks of oral copper supplementation or 5 days of IV supplementation (1 mg/day) is sufficient to correct the deficiency.[49,57]

Copper deficiency is assessed using serum copper concentrations along with CRP and ceruloplasmin, which appear to reflect changes in copper status in both copper-depleted and copper-replete individuals.[59] While reliable indicators of severe copper deficiency, serum copper and ceruloplasmin concentrations may not detect marginal copper deficiency because serum concentrations may be altered by a variety of conditions including inflammation (Table 164-7). Copper concentrations should be monitored every 2 to 6 months in patients receiving long-term PN. The chronic ingestion of excessive copper or inadequate elimination can result in cirrhosis as seen in Wilson's disease, an autosomal-recessive genetic disorder.

Chromium

Historically, trivalent chromium was thought to be essential for insulin function and maintenance of normal blood glucose concentrations. A low-molecular-weight chromium binding substance, *the glucose tolerance factor*, that may enhance insulin receptor response has been discussed. In 2014, the European Food Safety Authority (EFSA) determined that chromium is not an essential element in humans.[60] Chromium is stored in the heart, muscle, kidney, and liver and excreted in the urine.[49,52] Chromium deficiency may occur in patients receiving long-term chromium-free PN; symptoms include hyperglycemia, weight loss, and neuropathy.[49] Urine and serum chromium concentrations reflect chromium absorption not stores.[60] Chromium toxicity varies depending on the valence; trivalent chromium used in PN solutions is generally not toxic. No chromium toxicity has been reported in patients receiving PN, even though intake may be 30 to 60 times higher than estimated requirements through chromium contamination, primarily Dextrose 70%,; additional supplementation is rarely needed.[52] Chromium toxicity has only been reported with contaminated drinking water or industrial exposure. Chromium supplementation as an adjunct to aerobic exercise for weight loss or diabetes mellitus management is ineffective.[60,61]

Manganese

Manganese is needed as a cofactor for several metalloenzymes, including isocitrate dehydrogenase (Krebs cycle), superoxide dismutase (mitochondrial antioxidant), glutamine synthetase (astrocytes), arginase (urea cycle), pyruvate carboxylase (carbohydrate metabolism), glycosyltransferases (bone formation), and prolidase (wound healing).[50,62] Excess manganese is rapidly and efficiently eliminated in bile in the absence of significant cholestasis. Excretion may be compromised in newborns due to immature liver function. Manganese deficiency is only associated with the ingestion of chemically defined manganese-deficient oral diets. Table 164-7 lists symptoms associated with manganese deficiency.

Manganese toxicity is more concerning and has been described in industrial exposures via inhaled manganese (welding) and in patients receiving long-term manganese-supplemented PN in the setting of chronic cholestasis. Toxicity may occur in adults receiving more than 500 mcg/day and in children receiving more than 40 mcg/kg/day.[62] Manganese can accumulate in brain tissue; an intravenous dosage of 1.1 mg/day has been associated with brain deposition.[50] Because of its paramagnetic properties, manganese is detectable using MRI with increased signal intensity on T1-weighted images of the basal ganglia, especially in the striatum, globus pallidus, and substantia nigra. Manganese appears to target the dopaminergic (DAergic) neurons but may affect other neurotransmitters.[62] Whole-blood manganese concentrations are used to assess manganese status; serum concentrations do not correlate with either whole blood concentrations or MRI findings.[62] The neurodegenerative process induced by manganese is termed *manganism*. Symptoms mimicking Parkinson's disease, including psychiatric symptoms, cognitive deficits, motor impairment, extrapyramidal symptoms, headache, dizziness, rigidity, tremors, ataxia, and facial muscle spasms.[49,62] Lewy bodies, the hallmark of Parkinson's disease, are not seen in manganism.[62] Removing manganese from the PN solution results in resolution of neurologic symptoms with partial or total MRI normalization within 1 year.[62] The newborn brain may be more susceptible to the effects of manganese toxicity which has implications for manganese supplementation in premature neonates receiving PN.[62]

Molybdenum

Molybdenum is a cofactor for enzymes involved in catabolism of sulfur-containing amino acids, purines, and pyrimidines (xanthine, aldehyde, sulfite oxidases).[49,50,63] Molybdenum deficiency is uncommon, but a rare genetic defect that prevents sulfite oxidase synthesis resulting in molybdenum deficiency has been identified. A continuous supply of sulfated compounds is needed during brain development; thus, young infants are at risk if an adequate molybdenum supply is not provided.[63] Molybdenum deficiency may occur in patients receiving long-term molybdenum-free PN; although significant molybdenum contamination is present in all PN solutions. Currently, there is no IV molybdenum product marketed in the United States, and no marketed trace element combination product contains molybdenum. Molybdenum deficiency symptoms include tachycardia, tachypnea, headache, night blindness, nausea, vomiting, central scotomas, lethargy, disorientation, and coma (Table 164-7).[49,50,63] Symptoms reverse with molybdenum supplementation. Plasma and serum molybdenum are very low and difficult to measure, and plasma concentrations do not reflect molybdenum status.[52] Biochemical abnormalities expected in molybdenum deficiency include very low serum and urine uric acid concentrations (low xanthine oxidase activity) and low urine inorganic sulfate concentrations with high urine inorganic sulfite concentrations (low sulfate oxidase activity).[49,50] Molybdenum toxicity has not been described.

Iodine

Iodine, found primarily in the thyroid gland (70%-80%) incorporated into thyroid hormones, is required for normal thyroid function which affects resting energy expenditure and growth. In iodine deficiency, there is a constant release of thyroid stimulating hormone (TSH), resulting in thyroid gland hyperplasia and goiter formation. However, not everyone with an iodine-deficient diet will develop a goiter. The most serious effects of iodine deficiency are during pregnancy and in childhood, including fetal death, cretinism, abnormal growth, and mental retardation.[49] Measurement of thyroxine (T_4), tri-iodothyronine (T_3), and thyroid stimulating hormone (TSH) can be used to assess iodine status (Table 164-7). Iodine needs may be met by consumption of iodized salt or cutaneous iodine absorption from povidone–iodine, a topical antiseptic, used in catheter care.[50] Use of povidone–iodine for this indication has virtually been eliminated with the increased use of chlorhexidine for catheter site care, putting patients requiring long-term PN at risk. An IV iodine product is no longer available, and no trace element combination product marketed in the United States contains iodine. Iodine excess is rarely a clinical concern when thyroid and kidney function are normal except in overdoses or too rapid correction of iodine deficiency.[50]

Vitamins

Vitamins act as both catalysts (cofactors) and substrates in essential metabolic reactions. They are needed for normal growth, metabolism, and cellular integrity. They facilitate energy-yielding chemical reactions; they do not contribute energy. A thorough review of vitamins and their complex effects on nutrition and metabolism is beyond the scope of this chapter.[50,52,64] A comprehensive nutrition-focused history and NFPE are valuable means of assessing patients for vitamin deficiency or toxicity (Table 164-8). Generalized malnutrition is often associated with multiple vitamin deficiencies or increased needs; however, single vitamin deficiencies do occur. Thiamine (B_1) deficiency can result in early symptoms (dry or wet beriberi, GI symptoms) or advanced symptoms (lactic acidosis, Wernicke's encephalopathy, polyneuropathy, ataxia, mental confusion) due to impaired oxidative and energy metabolism often leading to serious and potentially irreversible neurological damage or death.[50,65] Macrocytic anemia, peripheral neuropathy, and neuropsychiatric sequelae may be caused by vitamin B12 (cyanocobalamin) deficiency which can occur after gastric or ileal resection due to the loss of intrinsic factor or absorption sites of the intrinsic factor-B_{12} complex, respectively. Vitamin B12 deficiency has been reported with increasing frequency in older adults, especially with prolonged gastric acid suppression with proton pump inhibitors.[66] There is a high prevalence of subclinical vitamin K deficiency in patients with chronic kidney disease, including those on hemodialysis or peritoneal dialysis. Vitamin K deficiency is a modifiable risk factor for cardiovascular disease and bone fracture in this patient population.[67]

TABLE 164-8

Assessment of Vitamin Status

Vitamin	Signs of Deficiency	Laboratory Assay	Comments
Water-Soluble Vitamins			
Thiamine (B1)	Early: anorexia, fatigue, depression, impaired memory or concentration Late: paresthesia, nystagmus, GI beriberi (nausea, vomiting, abdominal pain, lactic acidosis), beriberi (heart failure, edema),	Whole blood or erythrocyte transketolase activation test	Increased need with hemo- and peritoneal dialysis, alcohol misuse, malabsorption, hypermetabolism

	Wernicke's encephalopathy, Korsakoff's psychosis, peripheral neuropathy	Blood thiamine pyrophosphate Erythrocyte glutathione reductase activity coefficient	
Riboflavin (B2)	Mucositis, dermatitis, cheilosis, glossitis, photophobia, corneal vascularization, lacrimation, decreased vision, impaired wound healing and growth, normocytic anemia	Urine riboflavin	
Pantothenic acid	Fatigue, malaise, headache, insomnia, vomiting, abdominal cramps	Serum pantothenic acid	
Niacin	Pellagra: dermatitis, dementia, glossitis, diarrhea, memory loss, headaches	Urine niacin and N1-methylnicotinamide Erythrocyte NAD and NADP concentrations to determine "niacin number"	Flushing, nausea, and vomiting seen with hyperlipidemia treatment; increased need with hemo- and peritoneal dialysis
Pyridoxine (B6)	Pellagra, dermatitis, glossitis, cheilosis, distal limb numbness or paresthesia, convulsions, microcytic anemia	Plasma pyridoxal 5-phosphate Urine 4-pyridoxic acid	Sensory neuropathy and seizures with very high doses (>2 g/day)
Folic acid	Macrocytic anemia, diarrhea, glossitis, cheilosis, angular stomatitis, fatigue, difficulty concentrating, irritability, headache, palpitations, shortness of breath, heart failure, tachycardia, postural hypotension, lactic acidosis, neural tube defects, impaired cellular immunity, paranoid behavior	Serum or plasma folate (acute) Red blood cell folate (chronic) Serum homocysteine	Decreased with increased cellular/tissue turnover (pregnancy, malignancy, hemolytic anemia); masks diagnosis of vitamin B12 deficiency; decreases risks of neural tube defects
Cyanocobalamin (B12)	Pernicious (megaloblastic) anemia, glossitis, spinal cord degeneration, peripheral neuropathy, paresthesias, pancytopenia, personality changes, dementia, depression, psychosis	Serum cobalamin Plasma homocysteine Urine or plasma methylmalonic acid[a] CBC	Decreased absorption in older adults, distal ileal resection, loss of gastric intrinsic factor due to gastrectomy or long-term gastric acid suppression
Biotin	Dermatitis, depression, lassitude, somnolence	Urine biotin	
Ascorbic acid (C)	Enlargement or keratosis of hair follicles, impaired wound healing, anemia, lethargy, depression, bleeding, ecchymosis, scurvy	Plasma ascorbic acid Leukocyte ascorbate	GI disturbances, hyperoxaluria and kidney stones, excess iron absorption with excess intake; individuals who smoke need 35 mg/day more than nonsmokers; rebound scurvy with abrupt discontinuation after long-term high doses
Fat-Soluble Vitamins			
Vitamin A (includes retinol, retinal, retinoic acid, and retinyl esters)	Dermatitis, night blindness, xerophthalmia, Bitot spots[b], pruritus, follicular hyperkeratosis, excessive deposition of periosteal bone, hair changes, poor growth and wound healing, impaired resistance to infection Irreversible: punctate keratopathy, keratomalacia, corneal perforation	Serum retinol Serum retinol-binding protein Serum retinyl esters (toxicity)	Teratogenic, liver toxicity with excessive intake; alcohol use, liver disease, hyperlipidemia, and severe protein malnutrition increase susceptibility to adverse effects of high intake; β-carotene supplements recommended only for those at risk of deficiency (fat malabsorption); may reverse corticosteroid-induced poor wound healing

D	Rickets, osteomalacia, osteoporosis, muscle weakness, poor growth, hypocalcemia, immune dysfunction, cardiomyopathy	Serum 25-hydroxy-vitamin D	Elevated intake causes hypercalcemia, nephrocalcinosis, azotemia, poor growth; decreased concentration in uremia, older adults (especially in winter), and fat malabsorption
α-Tocopherol (E)	Hemolysis	Serum α-tocopherol Ratios of serum α-tocopherol to total lipids	Excess intake: hemorrhagic toxicity; increased risk of bleeding with anticoagulants; impaired leukocyte function
K	Bleeding (ecchymosis, petechiae, hematomas)	Prothrombin time INR	Anticoagulant therapy can be affected by supplements or diet

CBC, complete blood count; GI, gastrointestinal; INR, international normalized ratio; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate.

[a] Plasma methylmalonic acid concentrations increase with vitamin B12 deficiency.

[b] Bitot spots are spots which are oval, triangular, or irregular in shape and located superficially in the conjunctiva.

Patients with steatorrhea have an increased risk of fat-soluble vitamin (A, D, E, K) deficiencies. However, the increasing prevalence of vitamin D deficiency is a worldwide concern, including all ages, genders, and racial/ethnic groups. Risk for deficiency is higher in children and older adults, pregnant women, individuals with dark skin, patients receiving long-term PN, those living in temperate and higher latitudes, and those with disabilities or who are obese.[68] Laboratory assessment can confirm the clinical suspicion of a deficiency state. Vitamin D2 (ergocalciferol from plant-based sources) and vitamin D3 (cholecalciferol from conversion of cholesterol in the skin by ultraviolet light) are quickly converted to 25(OH)D via hydroxylation in the liver. The best marker for vitamin D deficiency is the serum concentration of 25(OH)D. Reference ranges for US laboratories are typically 20-100 ng/mL (50-250 nmol/L), but the optimal range is likely above 30 ng/mL (75 nmol/L) based on the concentration associated with parathyroid hormone (PTH) stimulation and calcium absorption efficiency.[68] The first indication of a deficiency is usually a decrease in circulating serum 25(OH)D. Subsequently, there is a decrease in urinary vitamin D excretion, which is followed by diminished tissue concentrations. Because the active form of vitamin D, 1,25(OH)$_2$D, is produced only when needed, not stored, and dependent on kidney function, intact PTH concentration, and calcium and phosphorus supply, it is not a useful marker of vitamin D stores but may be helpful if assessing the kidney's ability to hydroxylate to the active form.

Vitamin toxicity can occur, especially with fat-soluble vitamins, which are stored in the body. Vitamin D toxicity can cause significant hypercalcemia, hypercalciuria, and soft tissue calcifications leading to kidney and cardiovascular damage.[50] Vitamin A toxicity is associated with many signs and symptoms including effects on bone.[50] Water-soluble vitamins, except cyanocobalamin (vitamin B$_{12}$), are not stored; consequently, the toxicity risk is minimal unless ingested in very high doses. However, evidence suggests that even water-soluble vitamins may be associated with adverse medication reactions when taken chronically in high doses. Preconception folic acid supplementation is definitively associated with a reduction in neural tube defects.[69] Multivitamin supplementation containing folic acid does not prevent cardiovascular disease despite its effects on homocysteine concentrations.[70] With North Americans consuming large amounts of nutrition supplements, spending more than $15.5B (2020 USD) for them each year, clinicians should be alert for signs of inappropriate vitamin use and hypervitaminosis (see Table 164-8) and be prepared to discuss rational supplement use with all patients.[71]

Essential Fatty Acids

The human body can synthesize all fatty acids except the essential fatty acids, linoleic acid (an omega-6 fatty acid) and α-linolenic acid (an omega-3 fatty acid). EFAD can be prevented if approximately 5% (linoleic acid) and 0.6% (linolenic acid) of total energy is ingested as these fatty acids.[72,73] EFAD is rare in adults and children but can occur with prolonged lipid-free PN, severe fat malabsorption, very low-fat enteral feeding formulations or diets, high medium chain triglyceride-containing diets, and severe malnutrition, especially in stressed patients.[74] Although the time needed to develop EFAD is variable, symptomatic EFAD has occurred after only 4 weeks of lipid-free PN, and biochemical evidence can occur within 1 week.[74] The brain grows rapidly during the last trimester of gestation and the first 2 years of life. Large amounts of essential fatty acids are needed for central nervous system myelin synthesis. Thus, newborns, especially those born prematurely, who have limited to no fat stores, may develop EFAD more rapidly than adults and should generally receive a source of essential fatty acids within 72 hours after birth.[74] Symptoms reported with EFAD include dermatitis (dry, scaly skin), increased susceptibility to infection, impaired wound healing, poor growth and brain development, and immune dysfunction.[73,74]

Linoleic acid is converted to arachidonic acid (20:4ω-6; a tetraene fatty acid). When linoleic acid is unavailable, oleic acid (18:1ω-9) is the preferred substrate, resulting in production of eicosatrienoic acid (20:3ω-9; a triene fatty acid). Thus, EFAD is associated with decreased tetraene and increased triene production. Different methods to measure fatty acids have resulted in variable proposed threshold triene-to-tetraene (T:T) values to diagnose EFAD.[75] The usual T:T ratio is approximately 0.01 to 0.05 depending on the assay; thus a T:T ratio greater than 0.05 generally suggests early EFAD. The T:T ratio will be abnormal before there are overt clinical symptoms. Clinical symptoms of EFAD will be present in patients with higher T:T ratios. EFAD diagnosis is generally made based on risk assessment and/or clinical findings with confirmation by measuring serum fatty acid concentrations.

Carnitine

Carnitine is a quaternary amine required for transport of long-chain fatty acids into the mitochondria for β-oxidation and energy production. Additionally, acyl compounds that are trapped within cells due to cell membrane impermeability can be esterified with carnitine, forming acylcarnitine derivatives, which are transported out of the cell, preventing the acyl compounds from accumulating to toxic concentrations (detoxification). Carnitine is also important in the metabolism of intracellular acetyl coenzyme A.[76,77] The L isomer is the physiologic active form.

Carnitine is available from a wide variety of dietary sources (especially dairy products and meats) and can be synthesized when intake is low from lysine and methionine.[78] Carnitine is filtered by the kidney and reabsorbed in the proximal tubule.[79] Hepatic synthesis is decreased in premature infants, and low serum carnitine concentrations and overt carnitine deficiency have been documented in premature infants receiving carnitine-free PN or diets (secondary deficiency), as well as in those with primary deficiency due to carnitine inborn errors of metabolism (eg, defect in the OCTN2 transporter; biosynthetic defects).[78,79] Other predisposing factors for secondary carnitine deficiency include pregnancy, malabsorption (cystic fibrosis, short bowel syndrome), chronic disease (HIV, kidney, liver), chronic medication therapy (valproic acid, verapamil, zidovudine), and a vegetarian diet.[79,80]

The clinical presentation of carnitine deficiency varies by type but may include generalized skeletal muscle weakness, hypotonia, lethargy, gross motor delay, poor feeding, growth failure, hypoglycemia, seizures, encephalopathy, hepatomegaly, hyperammonemia, recurrent infections, cardiomyopathy, and coma.[78,79] Symptoms are typically more severe in patients with primary deficiency. In clinical practice, carnitine status is assessed by measuring the serum total and free carnitine concentrations along with acylcarnitine; although, carnitine is distributed primarily in the muscle. When only total and free concentrations are available, the free is subtracted from the total to give the acylcarnitine concentration. Serum and urine carnitine concentrations are most helpful in primary carnitine deficiency; acylcarnitine concentrations are more helpful in secondary deficiency.[79]

Daily supplementation of neonatal PN solutions with 2 to 5 mg/kg carnitine is recommended when no enteral source is provided.[52] Higher doses (100-200 mg/kg/day) may be required for treatment of primary deficiency.[77]

NUTRIENT REQUIREMENTS

⑦ Evidence-based patient-specific goals should be established considering the patient's clinical condition and the need for maintenance or repletion in adults and continued growth and development in children. Individual nutrient requirements vary with age, sex, size, and clinical condition. Nutrition status, physical activity, and the need for continued maintenance of adequate nutrition or repletion in those with ongoing metabolic stress or malnutrition dictate the nutrient requirements for an individual. For obese patients, usual nutrition requirements may be altered because of desired weight loss and after bariatric surgery. In children, sustaining or reestablishing normal growth and development is critical. Organ function (intestine, kidney, liver, pancreas) may affect nutrient utilization. Nutrient requirements can be estimated using various methods interpreted in the context of patient-specific factors.

Recommended Dietary Allowances

The Recommended Daily Allowances (RDAs) were first established in 1941. In 1997, the Food and Nutrition Board introduced a new designation for nutrition reference values, the Dietary Reference Intakes (DRIs). The four DRI categories are estimated average requirements (EARs), RDAs, adequate intakes (AIs), and tolerable upper intake levels (ULs). The nutrient intake that meets the needs of half of the healthy persons in a group (EAR) can be used for planning nutrient intakes for groups. The RDA, the nutrient intake that meets the needs of almost all persons in a designated group, is approximately two standard deviations above the EAR for nutrients for which the requirement is well defined and 1.2 times the EAR for other nutrients. To evaluate an individual's daily intake, the RDA is the most appropriate comparator. The AI, defined as the average intake for the designated group that appears to sustain growth or other indicator of health, is reserved for nutrients for which no EAR or RDA has been determined. The UL is the maximum nutrient intake unlikely to pose adverse effects in almost all persons in a designated group.[81] A new DRI category, Chronic Disease Risk Reduction level (CDRR), was recently added and defined as the nutrient intake that is expected to reduce the risk of developing chronic disease.[82] This new category has been applied to sodium and potassium guidelines.[83]

Dietary reference intakes have been established for six nutrient groups: calcium, phosphorus, magnesium, vitamin D, and fluoride; folate and other B vitamins; antioxidants (eg, selenium, vitamin C, vitamin E); trace elements; macronutrients (eg, protein, fat, carbohydrates, fiber); and electrolytes and water. An online Interactive DRI for Healthcare Professionals is available to calculate DRI-based nutrition needs for a generally healthy individual.[84]

In general, healthy adults and children older than 2 year of age should consume 45% to 65% of their total calories as carbohydrates. Protein recommendations also vary by age: 2 to 3 years, 5% to 20%; 4 to 18 years, 10% to 30%; and, adults, 10% to 35% of total calories. Recommended fat intakes vary by age: 2 to 3 years, 30% to 40%; 4 to 18 years, 25% to 35%; and, adults, 20% to 35% of total calories. Infants, especially premature infants, require a higher proportion of calories from fat (approximately 40%-50% of total calories) to ensure normal neurological development.

Energy

⑧ Validated predictive equations or population estimates are most often used to determine energy requirements; however, if available, indirect calorimetry is the most accurate bedside method to determine energy requirements. The method used will be determined by a variety of factors, including illness severity, resource availability, and clinician preference.

Estimating Energy Expenditure

Daily energy expenditure consists of the basal energy expenditure (BEE), diet-induced thermogenesis (10%), and energy used for physical activity. In sick or injured patients, the BEE is increased because of stress-related hypermetabolism, but the physical activity is usually greatly reduced. Continuous infusion EN, often used in critically ill patients, results in minimal diet-induced thermogenesis (not more than 5%) unless overfeeding. Failure to account for these changes can result in overfeeding.[22]

Numerous methods for determining an individual's daily energy requirement in a variety of settings have been published. These methods use population estimates of calories per kilogram of body weight (kcal/kg), equations that estimate energy expenditure (kcal/day or kJ/day; 1 kcal is equivalent to 4.184 kJ), or indirect calorimetry. The simplest and most convenient method to determine energy requirements is to use population estimates of calories required per kilogram of body weight. This method assumes standard values for health or the energy requirements associated with various disease states or clinical conditions, as well as the additional requirements for repletion of a malnourished individual. Most do not take into consideration age- or sex-related differences in energy needs. No stress or activity modifiers are used with these equations because the effect of the clinical condition (hypermetabolism) has been captured in the calculation. Daily adult requirements by this method can be estimated as shown below:[15,16,85]

Healthy, normal nutrition status, minimal illness severity:

$20-25\ \text{kcal ABW/kg/day}(84-105\ \text{kJ ABW/kg/day})$20–25 kcal ABW/kg/day(84–105 kJ ABW/kg/day)

Illness, metabolic stress (first 7-10 days of intensive care unit stay):

$12-25\ \text{kcal ABW/kg/day}(50-105\ \text{kJ ABW/kg/day})$12–25 kcal ABW/kg/day(50–105 kJ ABW/kg/day)

Illness, metabolic stress (BMI < 30 kg/m^2):

$25-30\ \text{kcal ABW/kg/day}(105-126\ \text{kJ ABW/kg/day})$25–30 kcal ABW/kg/day(105–126 kJ ABW/kg/day)

Illness, metabolic stress (BMI ≥ 30 kg/m^2):

$11-14\ \text{kcal ABW/kg/day}(46-59\ \text{kJ ABW/kg/day})\text{ or }22\text{ to }25\ \text{kcal IBW/kg/day}(92-105\ \text{kJ ABW/kg/day})$11–14 kcal ABW/kg/day(46–59 kJ ABW/kg/day)or 22 to 25 kcal IBW/kg/day(92–105 kJ ABW/kg/day)

Major burn [≥ 50% total body surface area (TBSA)]:

$25\ \text{kcal/kg ABW(kg)}+40\ \text{kcal per \% TBSA burned(adult) or }25-35\ \text{kcal/kg/day in non obese patients and }21\ \text{kcal/kg/day in obese patients}$

25 kcal/kg ABW(kg)+40 kcal per % TBSA burned(adult) or 25–35 kcal/kg/day in non obese patients and 21 kcal/kg/day in obese patients

When using the equations for individuals with a BMI over 30 mg/m^2, as the BMI increases, the number derived using ABW compared to IBW becomes quite disparate. Accuracy is improved by using the ABW recommendation for patients with BMI 30 to 50 kg/m^2 and the IBW recommendation when the BMI is greater than 50 kg/m^2. When these recommendations are used for patients with a BMI of 30 kg/m^2 or more, the calories provided allow for permissive underfeeding (provision of approximately 65% to 75% of usual estimated energy needs), which decreases infection rates and hospital lengths of stay.[22] DRIs for energy for healthy infants and children are shown in Table 164-9.[72] These maintenance energy requirements are approximately 130% to 150% of the basal metabolic rate, with the additional calories provided to support usual activity and growth. For all ages, energy requirements may increase with fever, sepsis, major surgery, trauma, burns, and long-term growth failure and in the presence of chronic conditions such as bronchopulmonary dysplasia, congenital heart disease, and cystic fibrosis.

TABLE 164-9

Dietary Reference Intakes for Energy and Protein in Healthy Children

Age (Reference age/weight)	Estimated Energy Requirement (kcal/day)[a]		Protein RDA (g/kg/day)[b]
	Boys	Girls	
0-6 mo (3 mo/6 kg)	570	520	1.52[c]
7-12 months (9 mo/9 kg)	743	676	1.5
1-2 yr (24 mo/12 kg)	1,046	992	
1-3 yr (24 mo/12 kg)			1.1
3-8 yr (6 yr/20 kg)	1,742	1,642	
4-8 yr (6 yr/20 kg)			0.95
9-13 yr (11 yr/M: 36 kg; F: 37 kg)	2,279	2,071	0.95
14-18 yr (16 yr/M: 61 kg; F: 54 kg)	3,152	2,368	0.85

F, female; M, male; RDA, recommended dietary allowance.

[a] 1 kcal is equal to approximately 4.18 kJ.

[b] Protein requirements in children with moderate to severe stress increase by 50% or more.

[c] Adequate intake.

There are many equations available to estimate energy expenditure in adults and children with an accuracy of approximately 40% to 77% when compared to indirect calorimetry

(Tables 164-10 and 164-11, respectively).[15,22,72,85–89] The Harris-Benedict equations, derived in 1919 from a study of 239 individuals, are still used by some clinicians for assessing energy requirements in adults. They have the advantage of incorporating the patient's age, height, weight, sex, and clinical condition. These equations were derived from oxygen consumption measurements made in normally nourished healthy individuals who were in a fasting and resting state. Although they are commonly referred to as the "BEE equations," they estimate resting energy expenditure (REE), the amount of energy expended at rest by a fasting, awake individual in a temperature-controlled environment performing only basal functions such as breathing, circulation, and metabolic processes.

TABLE 164-10

Equations to Estimate Energy Expenditure in Adults[a]

Healthy Adults
Harris-Benedict[b] Equations (kcal/day)
Men: BEE = 66 + (13.75W + 5H [cm]) – (6.8A)
Women: BEE = 655 + (9.6W + 1.8H [cm]) – (4.7A)
DRI Equations (kcal/day)[c]
Men: EER = 662 – 9.53A + (PA × 15.91W) + 539.6H (m)
Women: EER = 354 – 6.91A + (PA × 9.36W) + 726H (m)
PA = 1 if sedentary; 1.12 if low active; 1.27 if active; and 1.45 if very active
Mifflin-St. Jeor Equations (kcal/day)
Men: 10W + 6.25H (cm) – 5A + 5
Women: 10W + 6.25H (cm) – 5A – 161
Critically Ill Adults
Penn State Equation (kcal/day): Mifflin(0.96) + Tmax(167) + Ve(31) – 6212
Penn State Equation, modified (kcal/day) for **age ≥60 yr with BMI ≥30 kg/m2**: Mifflin(0.71) + Tmax(85) + Ve(64) – 3085

A, age in years; BEE, basal energy expenditure; BMI, body mass index; DRI, dietary reference intakes; EER, estimated energy requirement; H, height in centimeters or meters, as indicated; PA, physical activity factor; Tmax, maximum body temperature in the previous 24 hours in degrees centigrade; Ve, minute ventilation in L/min; W, actual body weight in kilograms; yr, years.

[a] No real consensus exists as to which formula is best in all situations. Many clinicians use more than one equation and calculate a range of acceptable intakes.

[b] The common practice of using an adjusted body weight for obesity in these calculations is not supported by the original data that used actual body weight in all cases up to a BMI of 56 kg/m^2 in men and 40 kg/m^2 in women.

[c] 1 kcal is equal to approximately 4.18 kJ.

TABLE 164-11

Equations to Estimate Energy Expenditure in Children[a,b]

FAO/WHO/UNU 2001 (kcal/day)[b]
0-12 Months
Breastfed
TEE (kcal/day) = –152 + 92.8W
TEE (MJc/day) = –0.635 + 0.388W
Formula fed
TEE (kcal/day) = –29 + 82.6W
TEE (MJc/day) = –0.122 + 0.346W
Boys 1-17 Years
TEE (kcal/day) = 310.2 + 63.3W – 0.263W2
TEE (MJc/day) = 1,298 + 0.265W – 0.0011W2
Girls 1-17 Years
TEE (kcal/day) = 263.4 + 65.3W – 0.454W2
TEE (MJc/day) = 1,102 + 0.273W – 0.0019W2
DRI Equations (kcal/day)
Birth through 2 years of age
EER = (89W – 100) + GF
GF = 175 kcal if 0-3 months; 56 kcal if 4-6 months; 22 kcal if 7-12 months; 20 kcal if 13-35 months
3-18 years of age
Boys: EER = 88.5 – (61.9A) + PA (26.7W + 903H) + GF
Girls: EER = 135.3 – (30.8A) + PA (10W + 934H) + GF
GF = 20 kcal if 3-8 years; 25 kcal if 9-18 years
PA = 1 if sedentary; 1.13-1.16 if low activity; 1.26-1.31 if normal activity; and 1.42-1.56 if very active

A, age in years; DRI, dietary reference intakes; EER, estimated energy requirement; FAO/WHO/UNU, Food and Agriculture Organization/World Health Organization/United Nations University; GF, growth factor; H, height in meters; PA, physical activity factor; TEE, total energy expenditure; W, actual body weight in kilograms.

[a] No real consensus exists as to which formula is best in all situations. Many clinicians use more than one equation and calculate a range of acceptable intakes.

[b] Additional daily calories are needed for growth; about 2 kcal/g of weight gain desired.

[c] 1 kcal is equivalent to approximately 4.18 kJ; 1 MJ = 1,000 kJ.

Because these equations approximate REE, the results have been modified by an activity or stress factor that adjusts for the individual's clinical condition. For example, an individual who is confined to bed may require a calorie intake that is only 20% to 30% above the REE, while a person who has sustained a severe burn injury may require 150% to 200% of the calculated REE. Multiplying the calculated REE by both a stress factor and an activity factor will overestimate needs because these equations overestimate REE by at least 6% to 15%.

Stress factors used in adults and children are shown in Table 164-12 and Table 164-13, respectively.[88] ABW (up to a BMI of 56 kg/m^2 in men and 40 kg/m^2 in women), not IBW or adjusted body weight, was used to generate the original data with these equations and thus should be used for these calculations.[22,86]

TABLE 164-12

Stress Factors for Use in Adults

Condition	Factor
No Stress	
Confined to bed	1.2
Out of bed: normal activity	1.3
Mild Stress[a]	
Postoperative recovery: uncomplicated surgery	1-1.15
Trauma: mild (eg, long-bone fracture)	1.2
Moderate Stress[a]	
Sepsis (moderate)	1.2-1.4
Trauma: CNS (sedated)	1.3
Trauma: moderate to severe	1.3-1.4
Severe Stress[a]	
Sepsis (severe)	1.3
Trauma: CNS (severe)	Up to 1.3
Burns (proportionate to TBSA burned)[b]	Up to 2.0

CNS, central nervous system; TBSA, total body surface area.

[a] Assumes decreased activity during periods of stress.

[b] Formulas specifically for estimating energy needs in burned children and adults have been published and are likely to be more accurate.

TABLE 164-13

Stress Factors for Use in Children

Condition	Factor
Well-nourished child at bedrest with mild-moderate stress	REE × 1.3
Normally active child with mild-moderate stress OR inactive child with severe stress (e.g., trauma, cancer) OR child with minimal activity and malnutrition requiring catch-up	REE × 1.5
Active child requiring catch-up growth OR an active child with severe stress	REE × 1.7

There is no individual method proven to accurately determine the energy needs of all critically ill patients (see Table 164-10). The Penn State equations appear to be most accurate in critically ill adults receiving mechanical ventilation. However, when compared to indirect calorimetry in mechanically ventilated patients, the accuracy of these equations has been shown to be only 34%.[90] The Penn State equations were found to have an accuracy rate of 77%, 70%, and 53% in older nonobese, younger obese (BMI ≥ 30 kg/m^2) and nonobese, and older obese patients, respectively. In older obese patients, use of the modified Penn State equation increased accuracy to 74%.[22,90] There is no consensus as to the best equation for critically ill adults who are not mechanically ventilated.

Measuring Energy Expenditure

The most accurate method to determine energy expenditure in clinical practice is to measure it using indirect calorimetry (metabolic gas monitoring), but capital and operational costs may limit its availability in many settings. Handheld calorimeters have been shown to be more accurate than predictive equations and may be a viable alternative to the more expensive equipment in both inpatient and outpatient settings.[91,92]

Indirect calorimetry methodology is based on pulmonary gas exchange: when a substrate (carbohydrate, fat, protein) is oxidized, heat is produced, oxygen is consumed, and carbon dioxide is expired in a constant amount depending on the substrate being oxidized. More carbon dioxide is produced when a gram of glucose is metabolized than either a gram of protein or a gram of fat. Indirect calorimetry is a noninvasive procedure in which oxygen consumption (VO_2, mL/min) and carbon dioxide production (VCO_2, mL/min) are measured, and the measured resting energy expenditure (MREE; kcal/day) is calculated using the modified Weir equation, as follows:[91–93]

$$MREE = ([3.94\, VO_2 + 1.11\, VCO_2] + [2.17\, uN_2]) \times 1.44$$

MREE=([3.94 VO2+1.11 VCO2]+[2.17 uN2])×1.44

The urinary nitrogen component (uN_2) is often omitted when calculating energy expenditure because it accounts for less than 4% of the energy expenditure, and its omission results in an insignificant measurement error.[86,91] Excluding the nitrogen component eliminates the need for a 24-hour urine collection, which can be difficult and delay the measurement.

The MREE represents the total energy expended during the period over which the measurements were taken extrapolated to a 24-hour period to approximate daily energy requirements. MREE reflects changes in energy requirements resulting from diseases or clinical conditions, but it does not include energy required for repletion of a malnourished individual or growth. No multiplier (activity/stress factor) should be used in critically ill adults.[82] Modifiers may be used in other settings (eg, weight loss clinics). In children, the MREE should be multiplied by a factor for physical activity or stress (Table 164-13).[88]

Indirect calorimetry can be used to determine the patient's respiratory quotient (RQ), calculated as VCO_2/VO_2, which reflects substrate utilization. RQ values for nutrient substrates are fat, 0.71; carbohydrate, 1; protein, 0.82; and mixed substrate (fat, carbohydrate, and protein), 0.85. An RQ value greater than 1 denotes either lipogenesis or hyperventilation; less than 0.7 may indicate a ketogenic diet, fat gluconeogenesis, or ethanol oxidation. Values outside the physiologic range of 0.67 to 1.3 suggest an invalid test. Clinically, the RQ is used to determine if a patient is being overfed, which is likely if the RQ value is greater than 1.[86] Increased carbon dioxide production with overfeeding leads to increased respiratory demand which can be decreased by reducing overall energy and carbohydrate administration.

Indirect calorimetry should be considered in any patient in whom uncertainty in estimating energy requirements needs to be minimized, such as adults and children who are severely malnourished (BMI < 18.5 kg/m^2) or obese (BMI ≥ 30 kg/m^2), who have unexplained high partial arterial pressure of carbon dioxide ($PaCO_2$) concentrations or minute ventilation, spinal cord injuries, who experience weight loss despite apparently receiving adequate protein and energy intakes, critically ill surgery patients receiving PN, patients with large total body surface area burns, and patients unable to be weaned from the ventilator.[20,92]

Indirect calorimetry may not be accurate in all clinical situations. Indirect calorimetry overestimates REE for patients with hyperventilation, metabolic acidosis, overfeeding, and if there is an air leak anywhere in the ventilator circuit. Underestimation of REE is likely with hypoventilation, metabolic alkalosis, underfeeding, and gluconeogenesis. Mechanically ventilated patients are technically easier to study because the indirect calorimeter can be integrated directly into the ventilator circuit. However, the patient must be at complete rest for 1 hour, must not receive bolus feedings either by enteral feeding tube or orally for 4 hours, should have no changes in substrate delivery for 12 hours, and must be on a fraction of inspired O_2 (FiO_2) of less than 0.6 with a positive end-expiratory pressure (PEEP) less than 10 cm H_2O (approximately 1.0 kPa) and peak airway pressure of less than 30 cm H_2O [2.9 kPa]) to ensure an accurate steady-state reading.[86,88] Newer indirect calorimeters may have less restrictions on ventilator settings, but many of the patients who would benefit most from indirect calorimetry often will not meet qualifications for the measurement.

Protein

⑨ Daily protein requirements are based on age, sex, nutrition status, disease state, and clinical condition. For adults, the RDA for protein is 0.8 g/kg/day, which is significantly less than most Americans typically consume.[72] In adults older than 60 years of age, protein needs are increased to 1.5 g/kg/day to reduce the loss of LBM that occurs with aging, and 1.5 to 2 g/kg/day or more may be needed in states of metabolic stress.[15,72,94] Protein requirements increase in pregnant and lactating women (1.1 g/kg/day or 6-10 g protein per day above the usual RDA). Table 164-9 lists the RDAs for protein for children.[72]

Protein metabolism depends on both kidney and liver function. Critical illness results in a hypercatabolic state in which there is both increased protein synthesis and degradation. The goal of protein administration is to minimize catabolism by maximizing protein synthesis. Consequently, protein requirements are increased to 1.2 to 2 g/kg/day in critically ill patients.[15,16] For obese critically ill patients, protein needs are 2 g/kg IBW if the BMI is between 30 and 40 kg/m^2 and 2.5 g/kg IBW or more if the BMI is greater than 40 kg/m^2.[15] Adults with significant burns have protein requirements of 2.5 to 3 g/kg ABW/day or more; children with burns required between 20% and 25% of their energy needs as protein.[89] Large stool or ileostomy losses increase protein requirements. Liver failure typically results in the need for protein restriction (0.5 g/kg/day) unless a hypercatabolic state is also present, which will increase requirements to 1.5 g/kg/day. Protein needs in patients with kidney failure are variable and affected by the various renal replacement therapies. The application of these protein intake guidelines requires both clinical judgment and frequent monitoring of kidney and liver function, serum chemistries, clinical condition, and nutrition outcomes.

Fat

The daily AI for men and women for α-linolenic acid is 1.6 and 1.1 g, respectively; for linoleic acid, it is 14 to 17 g/day for men and 11 to 12 g/day for women.[72] For adults, fat should represent no more than 10% to 35% of total calories, with the recommendation that saturated fatty acids, *trans* fatty acids, and dietary cholesterol intake be kept as low as possible while a nutritionally adequate diet is consumed. Fat should constitute 30% to 40% of energy in children 1 to 3 years of age and 25% to 35% of energy in children 4 to 18 years of age.[72]

Fat intake in children younger than 3 years of age is critical for proper central nervous system growth and development; generally, fat-restricted diets (skim milk) should not be imposed until after the age of 2 to 3 years except under medical supervision.

Fiber

Decreased serum cholesterol, improved glycemic control in patients with metabolic syndrome and type 2 diabetes mellitus, and maintenance of normal laxation have been attributed to dietary fiber intake, but only 5% of Americans consume the recommended amount of fiber daily.[95] Men and women 50 years of age and younger should ingest 38 g/day and 25 to 26 g/day of total fiber, respectively. For men and women older than 50 years of age, the AI is 30 g/day and 21 g/day, respectively.[72] The AI for fiber has not been set for children younger than 1 year of age. Breast milk and infant formulas are essentially fiber-free. For older children, the recommended fiber intake is 19 g/day for children 1 to 3 years of age, 24 g/day for children 4 to 8 years of age, and 26 to 31 g/day for children 9 to 13 years of age.[72]

Fluid

The daily fluid requirement for an adult depends on many factors but is generally estimated to be 30-40 mL/kg.[96] Fluid requirements per kilogram of body weight are higher for children and even higher for preterm infants because of their higher percentage of TBW and basal energy needs. Additionally, premature neonates have increased fluid requirements because of greater insensible losses and decreased concentrating ability of the kidneys. The Holliday-Segar method is a commonly used, quick, and simple method for estimating minimum daily fluid needs of children and adults. Children weighing less than 10 kg should receive at least 100 mL/kg/day. An additional 50 mL/kg/day should be provided for each kilogram of body weight between 11 kg and 20 kg and 20 mL/kg/day for each kilogram above 20 kg.[97] Thus, the minimum fluid required for a child weighing 8-kg would be 800 mL/day, a 17-kg child would need 1,350 mL/day; and a 50-kg individual would need 2,000 mL/day.

Factors that may alter fluid needs in both adults and children are listed in Table 164-14. All sources of fluid (and sodium) intake should be considered (eg, vehicles for IV medications, IV or feeding tube flushes) when determining fluid requirements. Urine output, sodium, and specific gravity as well as serum electrolytes and weight changes can be used to assess fluid status. A urine output of at least 1 mL/kg/h (in children) and approximately 0.5 mL/kg/h or 40 to 50 mL/h (in adults) is considered adequate to ensure tissue perfusion. Urine output should be higher if large fluid volumes or high renal solute loads (eg, concentrated PN or EN formulations) are being administered. Urine sodium will be low (≤20 mmol/L) if the patient has volume and/or sodium deficits. Urine specific gravity depends on the kidneys' concentrating and diluting capabilities. Concomitant diuretic therapy, resulting in increased solute or water excretion, may limit the use of urine specific gravity and sodium as assessments of fluid status.

TABLE 164-14

Factors That Alter Fluid Requirements

Increased Requirements	Decreased Requirements
Fever Radiant warmers Diuretics Vomiting Nasogastric suction Ostomy or fistula drainage Diarrhea Glycosuria Phototherapy Diabetes insipidus Increased ambient temperatures Hyperventilation Prematurity Excessive sweating Increased metabolism (eg, hyperthyroidism)	Fluid overload Heart failure Decreased urine output Heat shields Relatively high humidity Humidified air via endotracheal tube Kidney failure Hypoalbuminemia with starvation Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)

Micronutrients

Requirements for micronutrients (electrolytes, minerals, trace elements, vitamins) vary with age, sex, and route of ingestion (Table 164-15).[48–52,64,98,99] Enteral and parenteral requirements vary due to bioavailability considerations. Micronutrients poorly absorbed via the GI tract usually are required in greater amounts when given by the enteral than parenteral route. However, many water-soluble micronutrients are excreted more rapidly via the kidneys when administered intravenously. In these situations, the IV dose is greater than the enteral dose. Other factors that affect micronutrient requirements include GI losses through diarrhea, vomiting, or high-output fistula or ostomies; wound healing; and hypermetabolism or hypercatabolism. Cutaneous micronutrient losses (eg, zinc, copper, selenium) also may be significant after major burn injury. Sodium, potassium, magnesium, and phosphorus excretion are particularly dependent on kidney function, and in the setting of acute kidney injury or chronic kidney disease, intake will likely need to be restricted. Calcium needs, on the other hand, may be increased in these patients. Patients with moderate-to-severe malnutrition will have increased requirements during early refeeding owing to pre-existing deficiencies and rapid intracellular uptake with anabolism. Failure to provide adequate electrolyte replacement, especially potassium and phosphorus, and vitamin supplementation (thiamine) before advancing caloric provision can result in significant morbidity and even death from refeeding syndrome.[5,100,101]

TABLE 164-15

Recommended Daily Electrolyte, Trace Element, and Vitamin Intake in Healthy Individuals[a]

Nutrient	Adult (≥19 yr of age)[b]		Pediatric (≥6 mo of age)[c]	
	Enteral	Parenteral	Enteral	Parenteral
Electrolytes and Minerals				
Acetate[d]	—	—	—	—
Calcium	1,000 mg F (> 50 yr): 1,200 mg Lactating: 1,300[e]	0-15 mEq (0-7.5 mmol)	6-11 mo: 260 mg 12-36 mo: 700 mg 4-8 yr: 1,000 mg 9-18 yr: 1,300 mg	Premature: 2-4 mEq/kg (1-2 mmol/kg) Other: 1-2.5 mEq/kg (0.5-1.25 mmol/kg)
Chloride[d]		—	—	2-6 mEq/kg (mmol/kg)
Magnesium	M: 400-420 mg F: 310-320 mg Pregnant: 350-400 mg[e] Lactating: 310-360 mg	10-20 mEq (5-10 mmol)	6-11 mo: 75 mg 12-36 mo: 80 mg 4-8 yr: 130 mg 9-13 yr: 240 mg 14-18 yr: 360-410 mg	0.25-1 mEq/kg (0.12-0.5 mmol/kg)
Phosphorus	700 mg Pregnant, lactating (14-18 yr): 1,250 mg	20-45 mmol	6-12 mo: 275 mg 12-36 mo: 460 mg 4-8 yr: 500 mg 9-18 yr: 1,250 mg	Premature: 1-2 mmol/kg Others: 0.5-1 mmol/kg
Potassium	M: 3,400 mg F: 2,600 mg Pregnant, lactating (14-18 yr): 2,500-2,600 mg Pregnant, lactating (>18 yr): 2,800-2,900 mg	60-100 mEq (60-100 mmol) (1-2 mEq/kg [1-2 mmol/kg])	6-12 mo: 860 mg 12-36 mo: 2,000 mg F: 4-18 yr: 2,300 mg M (4-8 yr): 2,300 M (9-13 yr): 2,500 mg M (14-18 yr): 3,000 mg	2-5 mEq/kg (mmol/kg)
Sodium	2,300 mg	60-100 mEq (60-100 mmol) (1-2 mEq/kg [1-2 mmol/kg])	6-12 mo: 370 mg 12-36 mo: 1,200 mg 4-8 yr: 1,500 mg 9-13 yr: 1,800 mg 14-18 yr: 2,300 mg	2-6 mEq/kg (mmol/kg)

AT, alpha-tocopherol; DFE, dietary folate equivalent; F, female; IU, international units M, male; NA, not applicable; NE, niacin equivalents; RAE, retinol activity equivalents; TE, tocopherol equivalent

[a] Data represent either the Recommended Dietary Allowance (RDA), the Adequate Intake (AI), or the CDRR (Chronic Disease Risk Reduction level) for each nutrient.

[b] Intake in nonhealthy adults must be individualized.

[c] Term newborns, low-birthweight, and very-low-birthweight infants or older infants and children may have higher or lower requirements. Intake in nonhealthy children must be individualized.

[d] Not established; as needed to maintain acid–base balance.

[e] Pregnancy and lactation recommendations provided if different than age-specific recommendations; recommendations include pregnant or lactating females aged 14 to 50 yr unless otherwise specified.

[f] American Society for Parenteral and Enteral Nutrition recommendations

[g] May accumulate in cholestasis.

[h] No IV product available in the United States

[i] Additional intake needed with small bowel losses, which can be 12 mg zinc/L or 17 mg zinc/kg of stool or ileostomy output; an additional 2 mg/day needed for acute catabolic stress.

[j] 1 mcg RAE = 3.3 international units

[k] 40 international units = 1 mcg

DRUG–NUTRIENT INTERACTIONS

⑩ DNIs can affect response to medication therapy and nutrition status. A comprehensive discussion of DNIs is beyond the scope of this chapter.[102–105] Medication-induced nutrient deficiency, poor therapeutic response, enhanced toxicity, and failure to achieve desired nutrition outcomes can occur if either nutrition support or medication therapy is stopped because of adverse effects. Patient outcomes may be enhanced when an effective method to identify significant DNIs is coupled with a patient counseling program. An important part of the assessment process is to recognize risk factors that influence DNIs. The potential for significant DNIs is greatest in children and older adults. Other risk factors include critical illness, multiple medications, and EN.

Mineral and electrolyte serum concentrations may change because of medication therapy. For example, with loop diuretics, urine sodium, potassium, calcium, and magnesium wasting may occur, causing a reduction in their respective serum concentrations. Alternatively, calcium excretion is reduced with thiazide diuretics. Serum electrolyte concentrations also may increase as a direct result of the medication's mechanism (potassium-sparing diuretics) or because of the medication's salt form (sodium piperacillin/tazobactam). Corticosteroids and cyclosporine are known to cause hyperglycemia; other medications are prescribed to pharmacologically lower blood glucose concentrations (insulin, oral hypoglycemics).

Vitamin and trace element status also may be affected by medications (Table 164-16). For example, sulfasalazine therapy causes a decrease in folic acid, isoniazid therapy causes pyridoxine deficiency, and furosemide therapy may result in decreased thiamine concentrations. Medication therapy outcomes also may be affected by vitamin intake. For instance, the ingestion of high folic acid doses may decrease the therapeutic effect of methotrexate, and changes in an individual's usual vitamin K or vitamin E intake may cause variability in warfarin's anticoagulant effects.

TABLE 164-16

Drug–Nutrient Interactions

Medication	Effect
Angiotensin converting enzyme inhibitors	Increased urinary zinc losses
Angiotensin receptor blockers	Increased urinary zinc losses
Antacids	Thiamine deficiency
Antibiotics	Vitamin K deficiency
Aspirin	Folic acid deficiency; increased vitamin C excretion
Cathartics	Increased requirements for vitamins D, C, and B6
Cholestyramine	Vitamins A, D, E, and K and β-carotene malabsorption
Colestipol	Vitamins A, D, E, and K and β-carotene malabsorption
Corticosteroids	Decreased vitamins A, D, and C
Diuretics (loop)	Thiamine deficiency
Diuretics (thiazides)	Increased urinary zinc losses
Efavirenz	Vitamin D deficiency caused by increased metabolism of 25(OH)-vitamin D and 1,25-(OH)2-vitamin D
Histamine2 antagonists	Vitamin B12 malabsorption (reduced acid results in impaired release of B12 from food)
Isoniazid	Vitamin B6 and niacin deficiency
Isotretinoin	Vitamin A increases toxicity
Mercaptopurine	Niacin deficiency
Methotrexate	Folic acid inhibits effect
Orlistat	Vitamins A, D, E, and K malabsorption caused by fat malabsorption
Pentamidine	Folic acid deficiency
Phenobarbital	Increased vitamin D metabolism
Phenytoin	Increased vitamin D metabolism; decreased folic acid concentrations
Primidone	Folic acid deficiency
Protease inhibitors	Vitamin D deficiency (impaired renal hydroxylation)
Proton pump inhibitors	Decreased iron and vitamin B12 absorption (reduced acid results in impaired release of B12 from food)
Sulfasalazine	Folic acid malabsorption
Trimethoprim	Folic acid depletion
Warfarin	Vitamin K inhibits effect; vitamins A, C, and E may affect prothrombin time
Valproic acid	Zinc
Zidovudine	Folic acid and B12 deficiencies increase myelosuppression

Vehicles for medication delivery also may contain nutrients. Most IV therapies (maintenance IV fluids, medications, electrolyte replacements) are delivered using solutions of either dextrose (dextrose 5% or 10% in water) or sodium (0.9% NaCl). Lipid emulsion is used as the vehicle for the anesthetic agent propofol (10% lipid) and the IV calcium channel blocker clevidipine (20% lipid), and both contribute fat calories (1.1 kcal/mL or 4.6 kJ/mL for 10% and 2.0 kcal/mL or 8.4 kJ/mL for 20%) when these medications are used. Nutrition support regimens must be adjusted to accommodate calories, sodium, and other nutrients delivered through these therapies to avoid overfeeding, sodium overload, and other complications.

PRACTICAL GUIDELINES

The value of any marker used for nutrition screening is only as good as its ability to accurately identify malnourished patients and to correlate with nutrition-related complications. The response of the various nutrition status markers to nutrition therapy and the correlation between improvement in these markers and decreased morbidity and mortality support their validity. However, when applied to an individual, most of these markers lack specificity and sensitivity, which makes the development of a clinically useful, cost-effective approach to nutrition screening challenging.

The importance of the nutrition-focused history and NFPE in both nutrition screening and assessment cannot be overemphasized. Objective data such as weight can further substantiate the clinical impression and provide a baseline for subsequent monitoring. The cost effectiveness of many biochemical parameters is unknown. The assessment of other anthropometric measures is most useful in the setting of anticipated long-term nutrition support in which these measurements will serve as longitudinal markers of response to the nutrition care plan.

Better markers of nutrition status and methods for determining patient-specific nutrition requirements are needed to allow further refinement of estimates of an individual's nutrition needs. Functional tests and simple, noninvasive tests for body composition analysis hold promise for the future. However, until better methods of assessment become available and are demonstrated to be cost effective, the currently available battery of tests will continue to be the mainstay of nutrition assessment.

Initially, nutrition requirements are determined based on assumptions made about the patient's clinical condition and the nutrition needs associated with repletion or growth, if needed. After a nutrition intervention has been initiated, periodic reassessment of nutrition status is critical to determine the accuracy of the initial estimate. Nutrition requirements are dynamic in the setting of acute or critical illness—as the patient's clinical status changes, so will protein and energy requirements, further emphasizing the need for continued reassessment.

ABBREVIATIONS

ABW	actual body weight (kg)
AdjBW	adjusted body weight (kg)
AI	Adequate Intake
ALB	albumin
AND	Academy of Nutrition and Dietetics
ASPEN	American Society for Parenteral and Enteral Nutrition
BEE	basal energy expenditure
BIA	bioelectrical impedance analysis
BMI	body mass index
CDC	Centers for Disease Control and Prevention
CDRR	Chronic Disease Reduction Risk level
CRP	C-reactive protein
CT	computed tomography
DCH	delayed cutaneous hypersensitivity
DNI	drug-nutrient interaction
DRI	Dietary Reference Intake
DXA	dual-energy x-ray absorptiometry

EAR	Estimated Average Requirement
EFAD	essential fatty acid deficiency
EN	enteral nutrition
GI	gastrointestinal
HIV	human immunodeficiency virus
IBW	ideal body weight
IV	intravenous
LBM	lean body mass
MREE	measured resting energy expenditure
MRI	magnetic resonance imaging
MST	Malnutrition Screening Tool
MUMC	mid-arm muscle circumference
NFPE	nutrition-focused physical examination
PN	parenteral nutrition
RDA	Recommended Dietary Allowance
REE	resting energy expenditure
RQ	respiratory quotient
SCr	serum creatinine
SGA	Subjective Global Assessment
TBSA	total body surface area
TBW	total body water
TFN	transferrin
TUN	total urine nitrogen
UBW	usual body weight
UL	tolerable upper intake level
UUN	urine urea nitrogen
VCO_2	carbon dioxide production
VO_2	oxygen consumption
WHO	World Health Organization

SELF ASSESSMENT QUESTIONS

1. A 35-year-old woman (height, 168 cm [5′6″]; weight, 54.5 kg [120 lb]) with short bowel syndrome is admitted with mild dehydration and weight loss. She has lost 4.5 kg (10 lb) in the past 4 months. Which of the following would be the *most* appropriate characterization of her nutrition status?

   A. Normal, healthy

   B. Starvation-induced malnutrition

   C. Acute, disease-related malnutrition

   D. Chronic, disease-related malnutrition

2. An interdisciplinary nutrition support team is designing a nutrition screening program for their hospital. Which of the following would be a meaningful trigger to identify a patient at high risk for nutrition-related complications?

   A. Decreased oral intake for 3 days due to vomiting.

   B. Significantly decreased oral intake for the past 3 weeks due to anorexia.

   C. Planned weight loss of 4% of usual body weight (UBW) over the past 2 months.

   D. Weight loss of 5% of UBW due to acute diarrhea-induced dehydration.

3. Using ideal body weight (IBW), how would you characterize the nutrition status of a 50-year-old man whose weight is 60 kg (132 lb) and height is 183 cm (6′0″)?

   A. Normal, healthy

   B. Mild malnutrition

   C. Moderate malnutrition

   D. Severe malnutrition

4. A 69-year-old man weighs 75 kg (165 lb) and is 178 cm (5′10″). Based on his BMI, what is the *best* interpretation of his current nutrition status?

   A. Normal, healthy

   B. Overweight

C. Moderate obesity

D. Severe or morbid obesity

5. A patient with severe anorexia and moderate malnutrition is started on supplemental nutrition via a gastrostomy tube. Which serum visceral protein would be the most appropriate to measure the acute inflammatory response (first 7 days) in this patient?

A. Albumin

B. Transferrin

C. Prealbumin

D. C-reactive protein

6. A patient receiving long-term home parenteral nutrition (PN) has developed a tremor and aggressive behavior during the past 4 months. His PN includes a commercially marketed trace element solution which contains zinc, copper, manganese, and selenium. Routine laboratories are within reference ranges, except for elevated total and direct bilirubin and gamma glutamyl-transferase (GGT) concentrations. This patient's new onset symptoms are *most* consistent with which of the following nutrient imbalances?

A. Chromium deficiency

B. Copper toxicity

C. Zinc deficiency

D. Manganese toxicity

7. A patient with ulcerative colitis recently underwent colon resection with end ileostomy formation. His daily ostomy output has ranged from 900 mL to 2200 mL over the past 3 months. In clinic today, he states that his hair is falling out, and he has dry, cracked lips and a sore tongue. Which trace element abnormality would *best* explain his symptoms?

A. Selenium deficiency

B. Zinc deficiency

C. Chromium toxicity

D. Copper toxicity

8. An adolescent patient with cystic fibrosis is found to have an elevated serum alkaline phosphatase, but her other hepatic enzymes are within the reference range. She has normal kidney function. Which of the following laboratory tests should be evaluated to aid in the assessment of the increased alkaline phosphatase concentration?

A. Serum 25(OH)D

B. Serum 25$(OH)_2$D

C. Serum vitamin A (retinol)

D. Serum vitamin E

9. Using the kcal/kg method, which estimate of energy requirements is the *most* appropriate for a woman (weight, 90 kg [198 lb]; height, 165 cm [5′5″]) in the intensive care unit (ICU) with multiple injuries including head trauma suffered in a motor vehicle crash?

A. 1200 kcal/day (~5016 kJ/day)

B. 1800 kcal/day (~7520 kJ/day)

C. 2250 kcal/day (~9400 kJ/day)

D. 2700 kcal/day (~11,120 kJ/day)

10. A critically ill man (45 years old; weight, 145 kg [319 lb]; height, 185 cm [6′1″] is in the Surgical/Trauma ICU. Which of the following is the *most* appropriate initial assessment of this man's daily protein requirements?

A. 84 g

B. 150 g

C. 200 g

D. 290 g

11. A 9-year-old boy (weight, 23 kg [51 lb]) is admitted to the hospital and made NPO (nil per os) in preparation for surgery. He has no significant past medical history. Which of the following is the *most* appropriate rate to run his maintenance intravenous fluids?

    A. 29 mL/hour

    B. 38 mL/hour

    C. 65 mL/hour

    D. 96 mL/hour

12. A 45-year-old man (weight, 75 kg [165 lb]; height, 178 cm [5′10″]) is in the ICU after suffering several injuries in a drive-by shooting. He is receiving PN with 122 g of protein daily. A 24-hr urine was collected for a nitrogen balance study. The results are reported as total urea nitrogen (TUN) of 22 g N per 24 hr. What is this man's estimated nitrogen balance?

    A. Negative 2.5 (-2.5)

    B. Negative 3.5 (-3.5)

    C. Negative 4.5 (-4.5)

    D. Negative 6.5 (-6.5)

13. A 50-year-old man (weight, 80 kg [176 lb]; height, 178 cm [5′10″]) is receiving PN which provides a total of 2400 kcal/day (~10,000 kJ/day) and 75 g protein/day. The non-protein calories are distributed 60% CHO:40% fat. Indirect calorimetry was conducted. The results were reported as: REE 2210 kcal/day (~9240 kJ/day); RQ 0.95. Which of the following is the *most* appropriate interpretation of the current number of calories being provided in this patient's PN?

    A. An appropriate number of calories are being provided by his current PN.

    B. Too many calories are being provided by the current PN.

    C. Not enough calories are being provided by his current PN.

    D. There is not enough information provided to determine the adequacy of his calorie intake.

14. Which of the following nutrient imbalances is *most* likely to occur because of long-term proton pump inhibitor use?

    A. Vitamin B12 deficiency

    B. Vitamin D deficiency

    C. Thiamine deficiency

    D. Zinc deficiency

15. Which one of the following is required for the transport of free fatty acids into the mitochondria for ß-oxidation?

    A. Bile salts

    B. Pancreatic lipase

    C. Intestinal lipase

    D. Carnitine

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** This patient has malabsorption and a chronic disease state. Her weight loss was over more than 3 months which puts her into the chronic, disease-related etiological category for malnutrition.

2. **B.** A patient with decreased oral intake for more than 1 to 2 weeks would meet the criteria for being *at nutrition risk* in most of the available nutrition screens.

3. **C.** This patient's IBW is 77.6 kg (171 lb); his actual weight is 60 kg (132 lb). His actual weight is 77% of his IBW which would be classified as moderate malnutrition.

4. **A.** The patient's BMI is 23.7 kg/m^2 which would be classified as a healthy (normal) weight.

5. **C.** Prealbumin has the shortest half-life of the visceral proteins and responds most rapidly as an inflammatory marker.

6. **D.** Manganese accumulation in the basal ganglia has been associated with symptoms mimicking Parkinson's disease, similar to those being exhibited by this patient.
7. **B.** Alopecia, dermatitis, and glossitis are hallmarks of zinc deficiency. Zinc can be lost in significant quantities with high ostomy output.
8. **A.** Alkaline phosphatase is a marker of normal bone formation, elevations suggest possible vitamin D deficiency. The storage form of vitamin D, 25(OH)D, is the most appropriate to evaluate vitamin D status.
9. **A.** For a patient with a BMI of 33 kg/m^2, energy should be provided as 11 to 14 kcal/kg (46-59 kJ/kg) based on actual body weight or 22 to 25 kcal/kg (92-105 kJ/kg) based on IBW. Intake of 1200 kcal/day (5000 kJ/d) is 13.3 kcal/kg/day (55.6 kJ/kg/d) based on actual body weight.
10. **C.** For a critically ill patient with a BMI over 40 mg/m^2, the appropriate protein intake is 2.5 g protein per kg based on IBW. This man's IBW is 79.9 kg (176 lb), so he requires at least 200 g protein daily.
11. **C.** Maintenance fluids calculated using the Holiday-Segar method would be 1000 mL for the first 10 kg plus 500 mL for the next 10 kg plus 20 mL/kg for weight above 20 kg. Thus, 1000 mL + 500 mL + (20 ml/kg × 3 kg) = 1560 mL/day ÷ 24 hr/day = 65 mL/hr.
12. **B.** When TUN is available, nitrogen losses are estimated as TUN + 1.05. Thus, nitrogen balance would be Nin (122 g ÷ 6.25 g N per g protein) – Nout (22 + 1.05) = -3.5 g.
13. **B.** The REE of 2210 kcal/day (9250 kJ/d) should not be multiplied by any factor. PN provides 2400 kcal/day (10,000 kJ/d), so the patient is receiving too many calories.
14. **A.** Due to changes in acid in the stomach, the absorption of vitamin B12 can be affected by long-term use of proton pump inhibitors, especially in older adults.
15. **D.** The absorption of enteral fat depends on bile and lipase. However, the transport of free fatty acids into the mitochondria for energy production (by ß-oxidation) is a carnitine-dependent process.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 165: Parenteral Nutrition

Todd W. Mattox; Catherine M. Crill

KEY CONCEPTS

KEY CONCEPTS

1. Development and implementation of an appropriate, individualized nutrition care plan requires definition of nutrition goals, determination of nutrition requirements and appropriate route of nutrient delivery, and design of a monitoring plan to evaluate suitability of the nutrition regimen as a patient's clinical condition changes.

2. The appropriate route of nutrition support depends on the functional condition of the patient's gastrointestinal (GI) tract, risk of aspiration, expected duration of nutrition therapy, and clinical condition.

3. Suitable candidates for parenteral nutrition (PN) therapy can be identified on the basis of their age, nutrition status, expected duration of GI dysfunction, and potential risks of PN therapy.

4. PN formulations include injectable amino acids, dextrose, water, electrolytes, vitamins, trace elements, and other additives. Some formulations may include lipid injectable emulsion (ILE).

5. PN solutions may be appropriately formulated for administration by peripheral or central venous access.

6. PN formulations are available as standardized commercial multichamber bag products or they may be compounded with an automated compounding device (ACD).

7. PN solutions may be infused continuously or intermittently.

8. Biochemical and clinical measurements for effective monitoring of patients receiving PN include serum chemistries, vital signs, body weight, total daily fluid intake and losses, and nutritional intake.

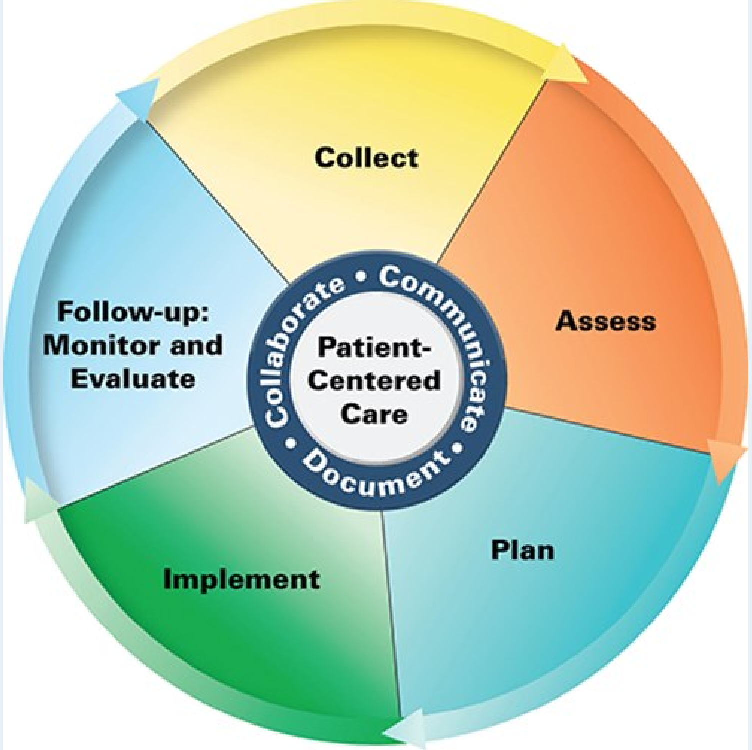
9. Non-catheter–related complications of PN therapy can be minimized by using age-appropriate nutrient dosing guidelines, frequent monitoring, and implementing rational adjustments to the PN regimen when metabolic abnormalities occur.

10. Individualized PN therapy should be based on nutrition therapy goals determined from a patient-specific nutrition assessment, type of available intravenous (IV) access, and macronutrient and micronutrient requirements.

11. A patient's nutrient requirements are affected by age, degree of metabolic demand, organ function, medication therapy, exogenous losses, acid-base status, and enteral intake in patients with recovering GI function.

PATIENT CARE PROCESS

Patient Care Process for Use of Parenteral Nutrition



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, race, sex)
- Patient history (past medical, surgical, family, social, alcohol use)
- Nutrition history (dietary history, weight history)
- Current medications (including nutritional supplements)
- Age appropriate objective data (Figure 165-3)
    - Height/length, weight, body mass index (BMI), head circumference
    - Fluid balance (intake and output)
    - Labs (eg, serum electrolytes, SCr, BUN, glucose, albumin, AST, ALT, alkaline phosphatase)
    - Vital signs (eg, temperature, pulse rate, respiration rate, blood pressure)

Assess

- Current nutrition status and time period of insufficient nutrient intake
- Clinical condition(s) preventing adequate oral nutrient intake
- Clinical condition(s) preventing use of enteral tube feeding to determine if an indication for PN therapy exists (Tables 165-1 and 165-2)
- Vascular access
- Current degree of metabolic instability (eg, hemodynamics, organ function, fluid/electrolyte status)
- Appropriate route of PN (central or peripheral)

Plan*

- Design an age-appropriate PN regimen that provides estimated nutrient requirements and minimizes risk of adverse medication reactions or worsening current metabolic conditions (see Designing a PN Regimen; Figs. 165-1 and 165-2)
- Monitoring parameters for efficacy (Fig. 165-3)

Implement*

- Provide education regarding all elements of treatment plan to patient/caregivers and other members of the healthcare team
- Use a standardized PN order form for ordering PN prescription to minimize risk of errors
- Verify the order to ensure that it is clear, complete, and correctly transcribed
- Confirm stability of formulation and compatibility of ordered nutrients and any non-nutrient medications
- Determine if PN solution will be provided as compounded sterile preparation according to United States Pharmacopoeia Chapter 797 standards or provided as a standardized, commercially available PN product
- Determine appropriate plan for patient-specific monitoring based on the patient's clinical condition to anticipate, prevent or treat mechanical/technical, metabolic/nutritional or infectious complications (Fig. 165-3)

Follow-up: Monitor and Evaluate

- Evaluate patient for mechanical, metabolic, and infectious complications (Fig. 165-3)
- Re-evaluate clinical condition(s) preventing adequate oral intake or precluding use of enteral tube feeding to anticipate either transition off of PN support or need for continuing PN therapy (Fig. 165-3)

** Collaborate with patient, caregivers, and other healthcare professionals.*

BEYOND THE BOOK

BEYOND THE BOOK

These audiovisual materials are useful to enhance student understanding regarding the COLLECT and ASSESS steps (video) as well as the PLAN, IMPLEMENT, and FOLLOW-UP: MONITOR AND EVALUATE steps (podcast) in the patient care process.

Video: Watch the video entitled "PN Appropriateness: The General Approach" at the American Society for Parenteral and Enteral Nutrition (ASPEN) website <http://www.nutritioncare.org/smartpn/>. This 13.5-minute video provides a brief overview regarding selection of appropriate PN candidates.

Podcast: Listen to the podcast entitled "When Times are Short: Managing Drug Shortages in PN" < https://soundcloud.com/user-67457490/when-times-are-short-managing-drug-shortages-mixdown?in=user-67457490/sets/parenteral-nutrition>. This podcast is just 14 minutes in length and discusses the approach to manage product shortages in PN support.

INTRODUCTION

Maintenance of adequate nutrition status during illness has been recognized for more than 50 years as an integral part of the treatment plan for patients who are unable to attain and sustain oral nourishment. Successful techniques for providing IV nutrition support were introduced to clinical practice in adults and subsequently, infants in the late 1960s.[1] Use of central venous access was investigated to reduce risk of metabolic complications associated with IV fluid overload and electrolyte imbalances. The use of large central vessels permitted infusion of concentrated formulas, which decreased the fluid volume required and avoided the phlebitis that commonly occurred when hypertonic infusions were given peripherally.

Clinical experience and research fostered development of protocols that promoted better patient care and resulted in a decline in complications and costs associated with parenteral nutrition (PN) therapy.[2] The scope of practice for nutrition support clinicians has broadened as a result of increasing knowledge regarding the metabolic consequences associated with acute injury and chronic disease states. The pharmacist's role in providing safe and effective nutrition-support care requires knowledge of the principles of patient selection, initial therapy design, outcome monitoring, and strategies for providing therapy during PN product shortages.[3–5] In addition, the pharmacist is uniquely prepared to take on the responsibility for PN order verification as well as compounding and dispensing of the PN admixture. The PN order must be verified by a pharmacist to ensure the order is clear, complete, and correctly transcribed. A clinical review should be performed to confirm appropriate indication, nutrient dosing, and non-nutrient medication dosing. A pharmaceutical review should be performed to confirm compatibility of ordered nutrients and any non-nutrient medications in addition to the expected stability of the formulation.[4,5] Other responsibilities of the nutrition support pharmacist may include development of policy and procedures as well as quality improvement activities for patient care and operational processes associated with providing PN and enteral nutrition (EN).[4,5] The clinical role of other healthcare professionals may be similar because of the evolving interprofessional approach to nutritional support.[6–10] This chapter reviews indications for PN, components of PN formulations, routes of IV administration, practical aspects of regimen design, solution admixture, outcome monitoring, and management of complications for both adult and pediatric (neonates, infants, and children) patients.

DESIRED OUTCOMES

① The primary objective of nutrition support therapy is to promote positive clinical outcomes of an illness and improve a patient's quality of life. Four fundamental steps are key to providing optimal care for patients who require nutrition support. They are establishing patient-specific nutrition goals, determining nutrient requirements to achieve the nutrition goals, assuring delivery of the required nutrients, and subsequently assessing the nutrition regimen.[5–7]

A patient's nutrition goals can be established after a thorough nutritional assessment (see Chapter 164). Nutrient requirements and an appropriate route for delivery of the required nutrients can then be determined. Nutrition support goals include correction of the patient's caloric and nitrogen imbalances and any fluid, electrolyte, vitamin, or trace element abnormalities. An additional goal is to lessen the metabolic response to injury by minimizing oxidant stress and favorably modulating immune response. These interventions should not cause or worsen other metabolic complications.

② The gastrointestinal (GI) tract is the optimal route for providing nutrients unless obstruction or other GI complications are present (see Chapter 166).[11] Two other considerations that may impact selection of the optimal route for delivery of nutrition support include expected duration of nutrition therapy and risk of aspiration. Patients who have nonfunctional GI tracts or are otherwise not candidates for EN may benefit from PN.

INDICATIONS FOR PARENTERAL NUTRITION SUPPORT

The association between malnutrition and development of complications and mortality is well documented for adult and pediatric patients.[7,11–13] Although various clinical nutrition markers are improved for patients who receive PN, the impact on clinical outcomes has been difficult to demonstrate in many adult populations. The effect of PN on complications and mortality is unclear.[11] Consensus guidelines for PN use for adults and pediatric patients are based on clinical experience and investigations in specific patient populations.[11–18] Unfortunately, a lack of consistency in published guidelines from different sources complicates identification of the patient who is most likely to benefit from PN.

③ PN use should not be determined by medical diagnosis or disease state.[11] However, there are more detailed considerations for specific disease states.[11–18] The decision to initiate PN is based on the findings of an assessment performed after a patient demonstrates an inability to meet nutritional needs enterally for an extended time period (Tables 165-1 and 165-2). This assessment must include an evaluation of the patient's nutrition status, clinical status, age, and potential risks of initiating therapy (eg, infection, metabolic abnormalities). The appropriate length of time to wait before starting PN therapy depends on patient's age and clinical status.[11–18] PN therapy is not an emergent intervention and should not be initiated until the patient is hemodynamically and metabolically stable.[11]

TABLE 165-1

Time Frame for Initiating Parenteral Nutrition

1. Adults
   a. Previously well-nourished patients: Initiate PN after 7 days of oral intake or EN less than 50% of estimated requirements
   b. Nutritionally at-risk patients (ie, involuntary loss of 10% or more of usual body weight within 6 months; involuntary loss of greater than or 5% or more of usual body weight in 1 month; involuntary loss or gain of 10 pounds within 6 months; BMI less than 18.5 kg/m^2; inadequate nutrition intake, including inadequate food or nutrition products for greater than 7 days): Initiate PN after 3 to 5 days of oral intake or EN less than 50% of estimated requirements.
   c. Moderate or severely malnourished patients: Initiate PN as soon as feasible for those in whom oral intake or EN is not possible or sufficient.
   d. Delay PN in metabolically unstable patients until improvement in clinical condition.
2. Neonates
   a. Very low birth weight infant (birth weight less than 1,500 g): Begin PN promptly.
   b. Critically ill: Initiate PN when EN is unable to meet energy requirements for energy expenditure and growth.
3. Pediatrics
   a. Infant, child, or adolescent with self-limited illness: Delay PN for up to 7 days.
   b. Infants: Initiate PN within 1 to 3 days when EN is unable to provide sufficient nutrients to support growth for an extended period.
   c. Older children and adolescents: Initiate PN within 4 to 5 days when EN is unable to provide sufficient nutrients to support growth for an extended period.

BMI, body mass index; EN, enteral nutrition; PN, parenteral nutrition.

Data from Reference 11.

TABLE 165-2

Indications for Parenteral Nutrition

1. Impaired absorption or loss of nutrients via the GI tract because of one or more of the following:
   a. Massive small bowel resection: Adult patients with less than 120 cm of small bowel distal to the ligament of Treitz without a colon or less than 60 cm of small bowel with an intact colon; neonates, infants, and pediatric patients who are unable to meet nutrient, electrolyte, and fluid requirements regardless of intestinal length.
   b. High output GI fistulae: Greater than 500 mL/day; location precludes enteral access.
   c. High volume fistula output with EN.
   d. Neutropenic colitis: Typhlitis or opportunistic infection in an immunocompromised patient.
   e. Small bowel mucosal disease: Radiation or chemotherapy-related enteritis, autoimmune enteropathy, intractable diarrhea of infancy.
   f. Intestinal atresia
   g. Gastroschisis
   h. Volvulus
   i. Meconium ileus
   j. Necrotizing enterocolitis
   k. Mesenteric thrombosis
2. Mechanical bowel obstruction: Intrinsic or extrinsic blockage of intestinal lumen.
   a. Stenosis or stricture
   b. Inflammatory disease
   c. Peritoneal carcinomatosis

   d. Severe adhesive disease
   e. Severe superior mesenteric artery syndrome
3. Restricted oral intake or EN necessary for bowel rest
   a. Ischemic bowel
      - Mesenteric artery stenosis
      - Abdominal compartment syndrome
      - Low flow states
   b. Severe pancreatitis
      - EN exacerbated pain
      - Worsening serum lipase levels
      - Infected pancreatic phlegmon/pseudocyst
      - Complex pancreatic fistula
      - Abdominal compartment syndrome
   c. Chylous fistula: High output with low-fat diet or elemental formula.
   d. Preoperative status: Severely malnourished patient with non-functional GI tract for 7 to 10 days prior to surgery.
4. Motility disorders
   a. Prolonged ileus
      - Diffuse peritonitis
      - Medical treatment-induced
      - Other disease states
   b. Pseudo-obstruction
   c. Scleroderma
   d. Visceral organ myopathy
   e. Very long segment Hirschsprung's disease
   f. Severe adhesive disease
5. Inability to achieve or maintain enteral access or EN
   a. Hemodynamic instability
   b. Active GI bleeding
   c. Severe neutropenic fever
   d. Low birth weight infant

EN, enteral nutrition; GI, gastrointestinal.

Data from Reference 11.

COMPONENTS OF PARENTERAL NUTRITION

④ PN formulations include IV sources of protein, dextrose, fat or lipid, water, electrolytes, vitamins, trace elements, and other additives. PN solutions should provide the optimal combination of macro- and micronutrients to provide a patient's specific nutritional requirements. Macronutrients include water, protein, dextrose, and lipid (Table 165-3). Micronutrients include vitamins, trace elements, and electrolytes. Both macronutrients and micronutrients are necessary for maintenance of normal metabolism. In general, macronutrients are used for energy (dextrose and lipid) and as structural substrates (protein and lipid). Micronutrients on the other hand support a variety of metabolic activities necessary for cellular homeostasis such as enzymatic reactions, fluid balance, and regulation of electrophysiologic processes.

TABLE 165-3

Macronutrient Components of PN Solutions

Nutritional Substrate	IV Source	Description
Fluid	Sterile water for injection USP	
Nitrogen	Crystalline amino acids	
	Standard solutions	Contain a balanced profile of essential, semi-essential, and nonessential L-amino acids
	Pediatrics	Amino acid profile includes standard essential, semi-essential, and nonessential amino acids with lower methionine, phenylalanine, and glycine concentrations; these solutions also contain taurine, glutamate, and aspartate
Energy		
Carbohydrate	Dextrose	
Fat	Lipid injectable emulsion • LCT emulsions • Fish oil emulsions • Mixed lipid emulsions	Fatty acid source • Soybean • Fish oil • Soybean-olive oil • SMOF (soybean oil, MCT, olive, and fish oils)

LCT, long-chain triglycerides; MCT, medium-chain triglycerides; PN, parenteral nutrition; SMOF, soybean oil, MCT, olive, and fish oils; USP, United States Pharmacopeia.

Over the past 5 to 10 years, there have been shortages of all PN components.[3] The unavailability of these products has resulted in delays in PN therapy initiation, restricted or limited nutrient dosing, and negative effects on all steps of the PN process that have compromised patient health and safety. Providing safe therapy during PN product shortages can be challenging for PN patients and practitioners.[3,5] Conservation recommendations and alternative therapy measures may need to be employed to optimize quality of care and avoid patient harm.[3,5] In addition, the Food and Drug Administration (FDA) may permit the temporary importation of PN products from foreign manufacturers that have been used safely and successfully in the foreign market. However, the products may have not received official FDA approval for routine use and distribution in the United States because the manufacturer has not sought FDA approval. Imported products have included PN components such as sodium glycerophosphate, multitrace element products, and amino acids.[3] If such products are imported and used in the United States, practitioners should thoroughly familiarize themselves with the prescribing information located in the product's package insert because of potential differences in product ingredients and concentration that may affect dosing. In addition, potential interactions resulting in stability or compatibility problems should be considered.

Amino Acids

Protein in PN solutions is provided in the form of crystalline amino acids (CAAs), which when oxidized for energy yield 4 cal or approximately 17 J/g of protein. However, including the caloric contribution from protein when calculating calories provided by the PN regimen is controversial.[19] While sufficient energy substrate should be provided to allow utilization of amino acids for protein synthesis rather than an energy source, oxidation of amino acids for energy has been demonstrated in critically ill patients and is thought to occur because of metabolic derangements seen during severe metabolic stress. Hence, some practice settings may differ in expressing calories provided by a PN regimen as total calories (protein, carbohydrate, and lipid calories) or non-protein calories (carbohydrate and lipid calories).

Commercially available CAA solutions may be categorized as standard amino acid solutions or modified amino acid solutions. Standard CAA solutions are designed for patients with "normal" organ function and nutritional requirements (see Table 165-3). Although standard CAA solutions differ in the proportion of specific amino acids, they contain a balanced profile of essential, semi-essential, and nonessential L-amino acids. Despite these differences, there are similar effects on markers of protein metabolism.[20] The protein concentration, total nitrogen, and electrolyte content may also differ among products. Because the nitrogen concentration of dietary protein is approximately 16%, 6.25 (100 g protein/16 g nitrogen) is commonly accepted as the conversion figure for calculating the nitrogen amount provided by CAA protein. Differences in nitrogen content per gram of amino acids among CAA products may affect calculation of nitrogen amounts infused when determining nitrogen balance.[20,21] The clinical significance of these differences in determining nitrogen balance for routine clinical use is unknown.[21]

Standard CAA solutions may also include obligatory electrolyte concentrations that may affect PN compounding as well as the total clinical dose provided to the patient.[22] CAAs are available in several different concentrations, which facilitate compounding of patient-specific PN regimens. Use of highly concentrated products (15%-20% amino acids) is attractive for critically ill patients who typically require fluid restriction but have large protein needs. Modified amino acid solutions are designed for patients who have altered protein requirements, such as neonates and pediatric patients (see Table 165-3). For example, several commercially available CAA solutions are designed to provide conditionally essential amino acids, which are considered nonessential during health because they are produced from other amino acids. However, under certain physiologic conditions, such as prematurity or sepsis, these amino acids cannot be synthesized in sufficient quantities.[20,22] CAA solutions specifically designed for neonates and pediatric patients contain increased amounts of taurine, aspartic acid, and glutamic acid. Other conditionally essential amino acids, such as cysteine, carnitine, and glutamine, are not available in commercial CAA solutions in pharmacologic amounts because they are relatively unstable or poorly soluble.[20,22]

Consequently, PN solutions may need to be modified to provide the desired amount of supplemental conditionally essential amino acids. For example, cysteine is a conditionally essential amino acid for preterm and term infants because of their enzymatic immaturity of the trans-sulfuration pathway. Cysteine may be added to PN solutions at the time of compounding as a supplement to CAA solutions and to enhance calcium and phosphate solubility by decreasing solution pH.[22] Carnitine is a quaternary amine required for long-chain fatty acid transport into the mitochondria for β-oxidation and energy production. Newborns are at risk for carnitine deficiency because of their immature biosynthetic capacity. Decreased plasma carnitine concentrations occur in infants and children receiving PN without carnitine.[16] Supplemental carnitine may be added to the PN solution at the time of compounding. Although the benefit of carnitine supplementation in PN has not been clearly identified, positive effects on nutritional markers, including improved fatty acid oxidation, weight gain, and nitrogen balance, have been documented. In general, carnitine supplementation is reserved for neonates expected to receive PN support for 7 days or longer.[16]

Glutamine is the most abundant free amino acid in the body and is an important intermediate for many metabolic processes. Glutamine has an important role in maintaining intestinal integrity, immune function, and protein synthesis during conditions of metabolic stress.[23] Positive effects on nutritional markers (eg, improved nitrogen balance) as well as outcome markers (eg, decreased length of hospitalization, incidence of infections, GI toxicities associated with chemotherapy or radiation) are associated with glutamine.[23] Unfortunately, the best candidate for response to glutamine therapy has not been clearly identified.[23,24] Use of both IV and enteral glutamine in combination with a variety of antioxidant supplements in critically ill adult patients has been associated with increased mortality.[24] Despite an association between increased brain volume and head circumference in school-aged children, who were premature at birth and received glutamine during the first year of life, the clinical usefulness of glutamine in neonates and infants is unclear.[23,25,26] Plasma glutamine concentrations increase with supplementation, but there is no beneficial effect on sepsis incidence or outcome, enteral feeding tolerance, necrotizing enterocolitis, growth, or mortality.[23,26,27] The clinical use of glutamine is further complicated because there is no parenteral glutamine formulation commercially available in the United States. Available CAA solutions do not contain glutamine because of poor solubility and instability.[22] Use of parenteral glutamine requires special manufacturing techniques not readily available in many institutional pharmacies.[23] However, parenteral glutamine has been made available from several licensed pharmacies that extemporaneously compound glutamine crystalline powder under sterile conditions either as a separate parenteral solution or as a part of a CAA solution.

Dextrose

The primary energy source in PN solutions is carbohydrate, usually in the form of dextrose monohydrate, hereafter referred to as dextrose which is available in concentrations ranging from 5% to 70%. When oxidized, each gram of dextrose provides 3.4 kcal (14.2 kJ). The appropriate IV dextrose dose depends on the patient's age, estimated caloric requirements, and clinical condition. For example, minimum dextrose requirements for neonates are estimated to be approximately 6 to 8 mg/kg/min and infusion rates should not exceed 14 to 18 mg/kg/min for infants or 4 to 7 mg/kg/min for adults.[16,28,29] The recommended dextrose dose for routine clinical care rarely exceeds 5 mg/kg/min for adolescents and adults.[16,28,29] Maintaining an age-appropriate dextrose infusion rate is necessary to minimize risk of adverse medication reactions. If the dextrose infusion rate exceeds the glucose oxidation rate, metabolically expensive pathways, such as glycogen repletion and lipid synthesis, are favored, resulting in increased energy expenditure, increased oxygen consumption, and increased carbon dioxide production. Excessive dextrose infusion rates also may contribute to the development of hyperglycemia and an increase in the concentration of biochemical markers indicative of fatty infiltration of the liver.[29,30]

Lipid Injectable Emulsion

Lipid injectable emulsion (ILE) is used as a concentrated source of calories and essential fatty acids.[31–35] Commercially available ILE products have traditionally contained soybean oil (SO) or a combination of SO and safflower oil. However, SO-based ILE may have negative effects on immune function and hepatic function, and this has led to approval of alternative mixed oil ILE for clinical use.[35,36] These products contain combinations of SO and olive oil, as well as SO, olive oil, medium chain triglyceride oil (MCT), and fish oil (FO), collectively known as SMOF.[32,33] An additional ILE alternative containing 100% FO is also approved for clinical use (Table 165-3).[34]

As a caloric source, ILE use may facilitate provision of adequate calories and minimize complications of nutrition therapy such as hyperglycemia, hepatotoxicity, or increased carbon dioxide production.[35] In the past, SO-based ILE has been used for treatment or prevention of essential fatty acid deficiency (EFAD) in both adult and pediatric patients because of the higher linoleic and linolenic FA composition.[35,36] EFAD is the result of a biochemical deficiency of linoleic acid and arachidonic acid, which are considered essential for humans.[28,35,36] Linoleic acid, an omega-3 FA, and linolenic acid, an omega-6 FA, are important for a variety of functions such as cellular integrity, platelet function, postnatal brain development, and wound healing.[36] Both are polyunsaturated long chain triglycerides (LCT). Normally, linoleic acid is converted to the tetraene arachidonic acid. When linoleic acid is not present in sufficient amounts, oleic acid is converted to the tetraene 5,8,11-eicosatrienoic acid, a FA of lesser physiologic integrity, and as a result, EFAD develops. EFAD may be prevented by providing 2% to 4% of total calories as linoleic acid and 0.25% to 0.5% of total calories as linolenic acid. This may be achieved for most adult patients by giving approximately 100 g SO ILE weekly and approximately 200 g mixed oil ILE weekly (based on approximately 2,000 calories/day [~8,400 J/day]).[35,36] Neonates and infants require a minimum of 0.5 to 1 g/kg SO ILE daily.[16] The SO-olive oil product is not approved for use in pediatric patients because of the lower linoleic and linolenic acid content and inadequate provision of essential fatty acids to prevent or treat EFAD when used in recommended doses.[32] In general, the 100% FO product is not indicated for treating EFAD because of the relatively lower essential FA content.[34,35] This product is indicated for use in pediatric patients with PN associated cholestasis.[34] However, EFAD may be prevented in PN-dependent infants who received FO ILE as the sole source of fat calories for at least 1 month.[37]

ILEs with SO as the lipid source may have negative effects on immune function as the result of omega-6 PUFA influence on proinflammatory eicosanoid production through arachidonic acid metabolic pathways.[35,36] Mixed oil ILE may promote lower production of proinflammatory cytokines by providing lower amounts of omega-6 FA. Olive oil–based ILEs provide essential fatty acids, are a rich source of vitamin E, and have a neutral effect on immune function because of the decreased amount of omega-6 PUFA linoleic acid.[35] MCTs may offer several advantages, especially for critically ill patients. MCTs are hydrolyzed and cleared more rapidly than LCTs, and they do not accumulate in the liver. In addition, MCTs do not require carnitine for entrance into mitochondria for oxidation. However, MCTs are not a source of essential fatty acids. IV MCT-LCT mixtures demonstrate safety and efficacy comparable with standard LCT emulsions.[35,36] FO–based ILE contain predominantly omega-3 PUFAs, which are metabolized to cytokine mediators that may be less inflammatory and immunosuppressive than those derived from omega-6 PUFAs. The clinical effect of FO-containing ILE administration on immune function, as well as on patient morbidity and mortality, is not clear.[35,36,38]

Phytosterols are sterols that are a natural component of plant-based oils used in ILE formulations.[39] SO-based ILE and phytosterol intake are associated with cholestasis of PN-associated liver disease (PNALD). SO-based ILE have a higher phytosterol content relative to the other mixed oil ILE products.[39] Use of mixed oil or 100% FO ILE in PN-dependent patients who developed cholestasis while receiving SO-based ILE may improve in or reverse of PNALD.[39]

Commercially available products are reviewed in Table 165-3. All commercially available ILE formulations contain egg phospholipids as an emulsifying agent and glycerol to make the emulsion isotonic.[22] Although the caloric contribution of fat is 9 kcal/g (38 kJ/g), the caloric content of 10% ILE is 1.1 kcal/mL (4.6 kJ/mL), 2 kcal/mL (8.4 kJ/mL) for 20% ILE, and 3 kcal/mL (12.6 kJ/mL) for 30% ILE because of the caloric contribution of the egg phospholipid and glycerol.

Commercially available ILE products may be administered by either the central or the peripheral route. They may be added directly to the PN solution as a total nutrient admixture (TNA), also referred to as a three-in-one system (lipids, protein, glucose, and additives), or they may be co-infused with the CAA-dextrose solution, commonly referred to as a two-in-one admixture.[5,31–34,40] However, 30% ILEs are only approved for use in the preparation of TNA and are not intended for direct IV administration.

Plasma ILE clearance is directly related to gestational age of infants and is influenced by the infusion rate and the patient's clinical status.[16] Rapid SO-ILE infusions contribute to decreased oxygenation for neonates.[41] Adverse pulmonary effects are thought to be caused by polyunsaturated fatty acid (PUFA)–driven prostaglandin production, which results in altered vascular tone. Although the association between ILE and pulmonary dysfunction is not clear, a boxed warning appears in the FDA product labeling for both SO and SO-olive oil ILE that acknowledges deaths in preterm infants associated with pulmonary fat accumulation thought to be related to ILE infusions.[31,32] In addition, rapid infusion of long-chain fatty acid formulations may have a negative impact on immunocompetence by saturating the reticuloendothelial system.[28,35,42]

Although the frequency of acute adverse medication reactions is less than 1% with current formulations, patients receiving their first ILE dose should be monitored for dyspnea, chest tightness, palpitations, and chills. Headache, nausea, and fever may also occur, especially with a rapid infusion rate. In general, ILE use is contraindicated for patients with an impaired ability to clear fat emulsion, such as patients with pathologic hyperlipidemia, lipoid nephrosis, and hypertriglyceridemia associated with pancreatitis.[31–35] Patients should be evaluated for hypersensitivity to any of the product-dependent ingredients such as fish, egg, soybean, or peanut protein prior to initiating ILE.[31–34,43]

ILE products remain the most common source of parenteral fat, but a number of medications have been introduced that contain lipid either as a vehicle for delivery or as a portion of the medication formulation. Propofol, an IV anesthetic, is delivered in a soybean-oil-in-water emulsion that has essentially the same composition and caloric concentration as 10% SO-ILE. This agent is used commonly for continuous sedation of mechanically ventilated patients and should be considered a potential source of calories that may require adjustment of a patient's nutrition regimen.[35,44] Clevidipine is an injectable calcium channel blocker that contains 20% ILE as a vehicle that may also be a potential source of IV fat when used as a continuous infusion for multiple days of therapy.[45] The antifungal amphotericin B is available in several lipid-containing combinations such as liposomal and lipid complex formulations. The caloric contribution from amphotericin B is generally small and not clinically relevant when used in standard doses.

Vitamins

The Nutrition Advisory Group of the American Medical Association (NAG-AMA) recommended in 1975 the daily parenteral supplementation of 13 essential (four fat-soluble and nine water-soluble) vitamins for pediatric and adult patients based on requirements for healthy people.[46]

Since these original recommendations, the NAG-AMA has revised the guidelines for children to primarily reflect changes for preterm infants requiring PN.[46] The FDA also mandated in 2000 changes in adult parenteral vitamin formulations (inclusion of vitamin K and higher doses of vitamins B_1, B_6, and C).[46] Vitamin K was not included in early multivitamin formulations due to the potential for drug-nutrient interactions in patients receiving anticoagulants. Although the NAG-AMA recommendation for vitamin K for adults is 2 to 4 mg weekly, only 150 μg/day was mandated to be included in newer formulations by the FDA.[47] However, in adult patients receiving long-term SO-ILE-containing PN with vitamin K–free parenteral multivitamins at home, supplemental vitamin K may not be necessary to maintain normal prothrombin times and plasma vitamin K concentrations.[48] Indeed, SO used in ILEs is a natural source of phylloquinone (vitamin K1). However, the other commercially available mixed-oil ILE formulations contain phylloquinone as well.[49] SO-ILE formulations contain the highest amount of vitamin K and the concentration is generally dependent on the SO concentration in the ILE.[35,47–49] Although current vitamin K-containing multiple-vitamin products should provide sufficient amounts to prevent adverse effects associated with vitamin K deficiency, supplemental vitamin K may be given intramuscularly or subcutaneously or added to the PN solution if needed.[47]

The 2012 ASPEN recommendations advocate for the continued availability of multivitamin products with and without vitamin K so that clinicians have the ability to withhold vitamin K supplementation in patients receiving warfarin therapy. Most adult parenteral multiple-vitamin products which are available commercially contain vitamin K. MVI-12, multivitamin infusion without vitamin K is available from Hospira, Inc. Lake Forest, IL. Two parenteral multiple-vitamin products are commercially available for use for pediatric patients. MVI-Pediatric (Hospira Inc.) and Infuvite Pediatric (Baxter Healthcare Corporation) are formulated to meet the revised NAG-AMA guidelines for infants weighing less than 1 kg (2.2 lb) and children up to 11 years. However, there are no commercially available injectable multivitamin products designed to specifically meet the unique requirements of premature infants, including higher vitamin A and lower doses of vitamins B_1, B_2, B_6, and B_{12}.

Vitamin requirements may be altered in malnutrition and other specific disease states or with certain medication therapies. Individual and combination products are available to provide additional or tailored supplementation, which may be necessary to prevent development of vitamin toxicities or deficiencies caused by altered metabolism or medication therapy.

The 2012 ASPEN recommendations question whether the vitamin D content of parenteral multivitamins is adequate to meet current Recommended Dietary Allowances (RDA) and advocate for the addition of a parenteral vitamin D product for PN-dependent patients who are unresponsive to additional enteral vitamin D supplementation.[46] In addition, the recommendations support the continued production of adult-injectable multivitamin products with and without vitamin K and for the supplementation of carnitine (2-5 mg/kg/day) in neonatal PN and choline in all patients receiving PN.[46]

Trace Elements

Many trace elements are an important part of metalloenzymes and function as cofactors in a variety of regulatory metabolic pathways.[50] Although 17 trace elements have demonstrated biologic importance, clear deficiency syndromes in humans have been described only for cobalt (as vitamin B_{12}), copper, iodine, iron, and zinc.[50–52] In 1979, the NAG-AMA recommended chromium, copper, manganese, and zinc supplementation for patients receiving PN.[46,50] Recommendations followed in 1984 to also supplement with selenium.[46,50] Although there is not a clear deficiency syndrome for manganese, the NAG-AMA considered manganese essential based on case reports of patients receiving PN with metabolic complications that corrected after manganese supplementation. Reports of deficiency syndromes associated with selenium and molybdenum suggest that they may also be essential.[46,50,51] Although iodine deficiency does not occur for patients receiving short-term PN, it has been observed in patients receiving long-term PN and may be related to the use of chlorhexidine for central-line care instead of povidone-iodine.[46,50,52]

Injectable trace elements are available as single-trace element solutions and as multiple-trace element combinations.[22] The use of single-entity injectable products allows for individualization of trace mineral supplementation of chromium, copper, iodine, manganese, selenium, and zinc. Requirements for trace elements vary on the basis of the patient’s clinical condition. For example, higher doses of supplemental zinc are likely necessary for patients with high-output ostomies or diarrhea because the GI tract is the predominant excretion route for zinc. Whereas manganese and copper are excreted through the biliary tract, chromium, molybdenum, and selenium are excreted renally. Hence, these trace elements should be restricted or withheld from PN solutions for patients with cholestatic liver disease and kidney disease, respectively. ASPEN recommended formulation changes to the available injectable multiple-trace element preparations for PN patients.[46] In general, the recommendations support overall decreased trace element contamination in large- and small-volume PN products.[46] The recommendations advocate for decreased copper and manganese, no (or decreased) chromium, and inclusion and increased dose of selenium in all injectable adult multiple-trace products.[46] The recommendations also support products with no chromium, decreased manganese, and the inclusion of selenium in all injectable pediatric multiple-trace products.[46] These recommendations were recognized by injectable trace element manufacturers and reformulated products for adults and pediatric patients are now available.[22] The trace element combination product for adults provides the daily requirements for the trace elements considered essential by the NAG-AMA except chromium (ie, copper, manganese, selenium, zinc).[53] Chromium amounts provided as a contaminate in PN injectable products are considered adequate to meet daily requirements.[46] The combination product approved for use in the United States for neonates and pediatric patients contains zinc, copper, manganese, and selenium.[54] The addition of single-entity zinc, copper, and selenium is required in many pediatric weight ranges to meet recommended needs when using these combination products.

Electrolytes

Electrolytes such as sodium, potassium, calcium, magnesium, phosphorus, chloride, and acetate are necessary PN components for the maintenance of many cellular functions. Electrolytes may be given to maintain normal serum concentrations or to correct deficits. Patients who have "normal" organ function and relatively normal serum concentrations of any electrolyte should receive "normal" maintenance electrolyte doses when PN is initiated and daily thereafter. Specific electrolyte requirements vary according to the patient's age, disease state, organ function, previous and current medication therapy, nutrition status, and extrarenal losses. Electrolytes are available commercially as single- and multiple-nutrient solutions.[22] Multiple-electrolyte solutions are useful for stable patients with normal organ function who are receiving PN. Concentrated multiple-electrolyte solutions designed for addition to PN solutions generally contain only sodium, potassium, calcium, and magnesium. Phosphorus must be added as a separate additive. Further information regarding metabolism and requirements of vitamins, trace elements, and electrolytes is given elsewhere.[55]

DESIGNING A PARENTERAL NUTRITION REGIMEN

⑤ Several factors, including the patient's venous access, fluid status, and macronutrient and micronutrient requirements, are important considerations when designing the PN regimen. A patient's venous access and fluid status determines the maximum PN osmolar concentration, which will impact the nutrient amount that may be provided. PN solutions may be administered by central or peripheral venous access. The patient's clinical condition determines which route is most appropriate.

PN formulations may be provided as a two-in-one admixture that contains dextrose, CAA, and other necessary micronutrients or as a three-in-one admixture or TNA that contains dextrose, CAA, and ILE, as well as other necessary micronutrients. Use of TNA solutions offers several potential advantages, including reduced inventory (infusion pumps, tubing, and other related supplies), decreased time for compounding and administration, a potential decrease in manipulations of the infusion line (which should correspond with a decreased risk of catheter contamination), and ease of delivery and storage for patients receiving home PN.[40] Potential disadvantages include increased risk of infections and stability and compatibility concerns. For example, the stability of TNA admixtures is less predictable than that of two-in-one admixtures, which makes their use less desirable in some patient populations such as neonates and infants.[41,56]

Routes of Parenteral Nutrition Administration

Peripheral Route

Peripheral parenteral nutrition (PPN) is an option for mild-to-moderately stressed patients in whom adequate GI tract function is expected to return within 10 to 14 days.[11] PPN may also be used as a temporary source of PN, or as a bridge therapy during transition periods where oral intake or EN is suboptimal or clinical circumstances do not justify placing a central venous catheter (CVC) access.[11] In general, potential PPN candidates should not be fluid-restricted or require large nutrient amounts. Lower concentrations of amino acids (3%-5% final concentration), dextrose (5%-10% final concentration), and micronutrients compared with central parenteral nutrition (CPN) must be used for peripheral administration. Because PPN solutions are relatively dilute, larger volumes are usually necessary to provide nutrient requirements. Additionally, many patients who receive PPN likely will require ILE to achieve the desired caloric intake at levels consistent with CPN regimens. The primary advantages of PPN include a potentially lower risk of infectious and technical complications associated with CVC access.[11] Patients who are likely to be poor candidates for PPN include those with poor venous access as the result of multiple courses of chemotherapy, malnutrition, illness of long duration that has required multiple venous accesses for fluid and medication administration, premature infants, and the elderly. PPN use is also limited by relatively poor peripheral vein tolerance to hypertonic solutions. Thrombophlebitis is a common complication for patients receiving PPN.[56] Although the risk of phlebitis is greater with solution osmolarities greater than 600 to 900 mOsm/L, peripherally administered TNA with much higher osmolarities to adults has been associated with low infusion-site complications in some centers.[56,57] Efforts to minimize development of phlebitis or infiltration sequelae for patients receiving PPN include addition of ILE as a possible venous lumen protectant, subtherapeutic heparin doses (0.5-1 unit/mL) to prevent thrombus formation, or small doses of hydrocortisone (5 mg/L) to minimize access site inflammation.[56,57] However, the coinfusion of ILE with PPN (ie, not provided as a TNA) does not reduce phlebitis. In addition, heparin does not reduce catheter-related thrombosis and is not compatible for use in

TNAs.[56] Midline catheter use may offer some advantage and has been associated with a reduced risk of thrombophlebitis.[11,58] Although these catheters are not central venous access devices, they are longer and infuse into larger venous vessels that may dilute the PPN solution to a more tolerable osmolarity. The osmolarity of a PN solution may be estimated by using the guidelines for osmolarities of selected PN components listed in Table 165-4.

TABLE 165-4

Osmolarities of Selected Parenteral Nutrients

Nutrient	Osmolarity
Amino acid	100 mOsm/%
Dextrose	50 mOsm/%
Lipid emulsion (20%)	1.3-1.5 mOsm/g
Sodium (acetate, chloride)	2 mOsm/mEq
Sodium phosphate	3 mOsm/mEq sodium
Potassium (acetate, chloride)	2 mOsm/mEq
Potassium phosphate	1.7-2.7 mOsm/mEq potassium
Magnesium sulfate	1 mOsm/mEq
Calcium gluconate	1.4 mOsm/mEq

Central Route

CPN is the preferred route for PN delivery and is used predominantly for patients who require PN for periods of more than 7 to 14 days during hospitalization or indefinitely at home.[11,59,60] These patients may have large nutrient requirements; poor peripheral venous access; or fluctuating fluid requirements, such as metabolically stressed patients with extensive surgery, trauma, sepsis, multiple-organ failure, or malignancy. CPN solutions are highly concentrated hypertonic solutions that must be administered through a large central vein. Unlike peripheral veins, central veins have a higher blood flow, which quickly dilutes the hypertonic solutions. Disadvantages of CPN include risks associated with catheter insertion, routine catheter use, and care of the access site. Relative to peripheral venous access, CVC access is associated with a greater potential for infection. In addition, the risk of more serious catheter-induced trauma and related sequelae and other serious technical or mechanical problems is greater than that with peripheral access.

The choice of central venous access site depends on a number of factors, including the patient's age and anatomy. CVCs vary in composition, lumen size, number of injection ports, and other features that affect ease or convenience of care and maintenance. CVCs for short-term use for adults are commonly inserted percutaneously into the subclavian vein and advanced so that the tip is at the superior vena cava.[58] If this approach is not possible, the internal jugular vein can be used. Frequently, short-term central venous access is obtained for critically ill neonates via a catheter placed in the umbilical vein. Other sites for central venous access in infants and older children are similar to those in adults. When therapy is expected to last longer than 4 weeks, the catheter is tunneled subcutaneously before entering the central vessel, secured initially with retaining sutures, and anchored in place with a felt cuff that promotes subcutaneous fibrotic tissue growth around the catheter. The injection port may remain external or may be concealed entirely beneath the skin. Implanted CVCs have a larger port or reservoir that is surgically placed beneath the skin surface and anchored in the chest wall muscle. Peripherally inserted central catheters (PICCs) are venous access devices that are inserted into a peripheral vein (basilic, cephalic, or brachial) and advanced so that the tip is at the superior vena cava.[58] PICCs are increasingly used for both short- and long-term central venous access in acute or home care settings because of ease and economy of bedside placement.[11,58,60]

Constructing a Parenteral Nutrition Regimen

After the route of delivery is chosen, the components of the PN regimen are determined based on the patient’s nutritional assessment. Although not recommended due to increased potential for errors, some healthcare systems may require the entire PN order to be written in individual components and additives on traditional paper order forms without the use of a standard order form. Standardized electronic PN orders suitable for computerized prescriber order entry (CPOE) are recommended for all patients to minimize risk of errors associated with the ordering process.[5,61] Standardized order forms or clinical decision support within electronic PN ordering systems promote education of practitioners by providing brief guidelines for initiating PN and foster cost-efficient nutrition support by minimizing errors in ordering, compounding, and administration.[5,56,61] Standardized order forms also may include options for ordering certain related procedures, laboratory tests, protocols for patient management, or consultations with other medical services related to the patient’s nutrition support.

Adult Parenteral Nutrition Solutions

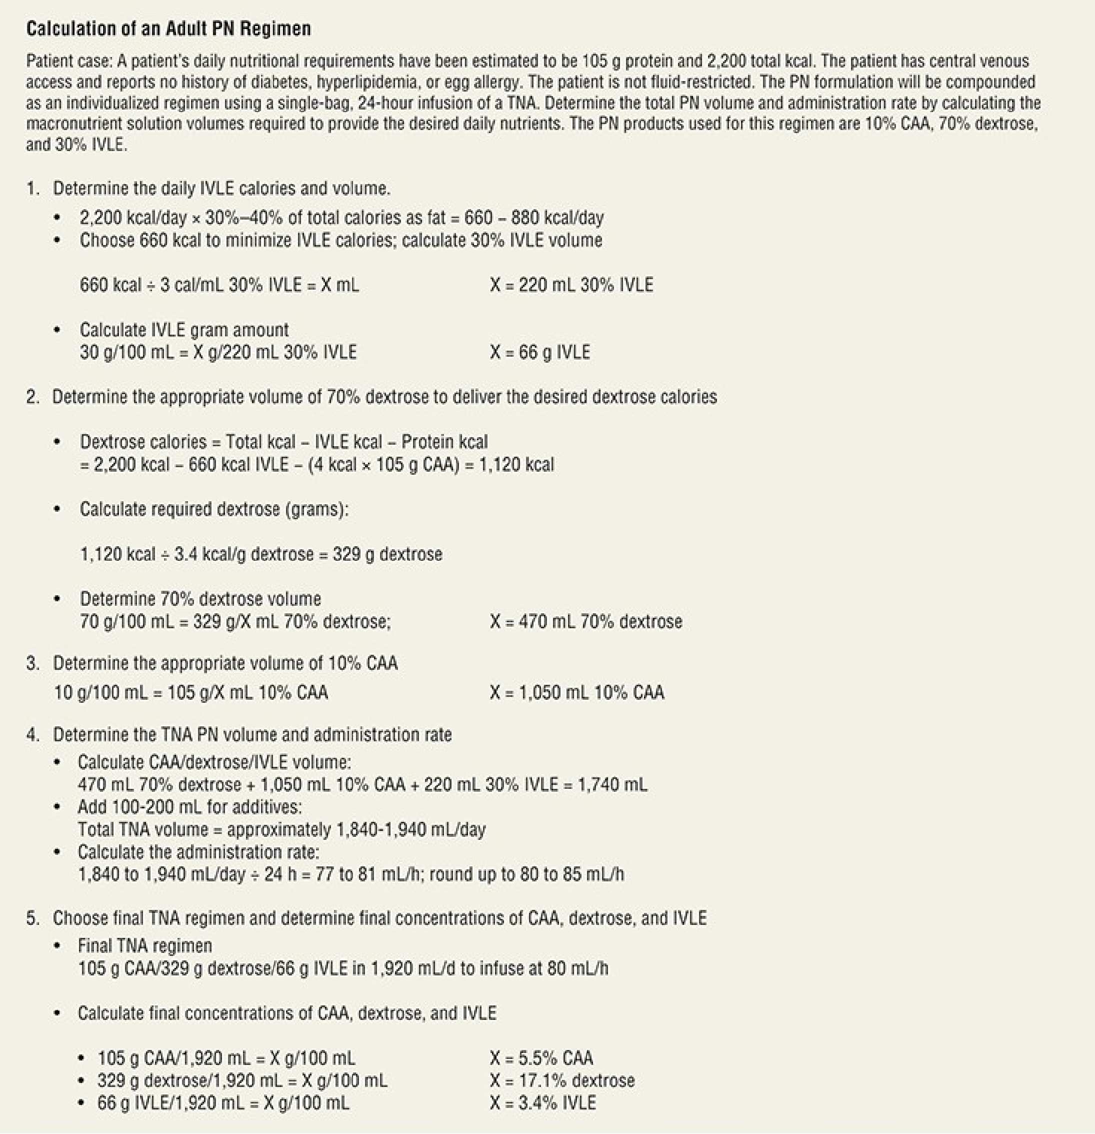
⑥ In general, there are two methods for ordering adult PN. The “standard formula approach” offers a variety of admixtures with a fixed nonprotein-calorie-to-nitrogen ratio. This method usually includes different formulas for mild-to-moderately stressed patients, and those who have kidney or liver failure or are fluid-restricted. Because the nonprotein-calorie-to-nitrogen ratio is fixed, the daily amount of nutrient delivered depends solely on the volume infused. Standard institutional PN formulations may be compounded; however, standardized commercial PN products or multichamber bag PN solutions are available from several manufacturers.[62] A standard institutional formula may promote clinician prescribing of a complete, balanced formulation and promote consistent provision of stable and compatible admixtures. However, efficiencies associated with use of the standard formula approach may be hindered if there is a frequent need to modify the PN formulation. Finally, standard PN formulations may be difficult to use in complicated patients, such as neonatal or pediatric patients, and those with severe malnutrition, organ failure, glucose intolerance, large GI losses, or critical illness.[62]

The “individualized formula approach” permits compounding of patient-specific admixtures. Compounding of the PN admixture is limited only by the concentrations of stock solutions and stability of the additives. The nutrient amount delivered depends on the daily volume of the PN solution infused and the nutrient amounts in the PN solution. The total daily amount of PN solution may be prepared in multiple bags or more cost-effectively in a single container.[40]

Historically, adult PN formulations were ordered by expressing the final concentrations of each component in the solution. However, this inconsistency may promote confusion and misinterpretation of PN admixture contents that may result in harm, especially when patients are transferred between health system environments. To ensure that PN labels in all health system environments clearly and accurately reflect the PN admixture contents, guidelines for standardized adult PN labeling have been recommended.[5,61] In addition to including a variety of other information on the label such as dosing weight and administration route, the guidelines recommend expressing PN ingredients in amounts per daily volume, which minimizes the need for pharmaceutical calculations to determine the nutrient value of the admixture. For example, macronutrients ordered in grams per day and electrolytes in milliequivalents or millimoles per day in an adult patient. Commercially available computer software for calculating PN formulations include the recommended ASPEN labeling guidelines (Baxter Healthcare, Deerfield, Il.; B. Braun Medical Inc., Bethlehem, PA).[5,61] Pharmaceutical calculations of an adult TNA PN regimen are briefly reviewed in Fig. 165-1.

FIGURE 165-1

Calculation of an adult PN regimen. To convert to energy units of kilojoules (kJ) multiply values with kilocalories as the numerator (kcal, kcal/mL, kcal/kg, kcal/g) by 4.18 to give the corresponding value in kilojoules (kJ, kJ/mL, kJ/kg, kJ/g). (CAA, crystalline amino acids; ILE, lipid injectable emulsion; PN, parenteral nutrition; TNA, total nutrient admixture.)



Calculation of an Adult PN Regimen

Patient case: A patient's daily nutritional requirements have been estimated to be 105 g protein and 2,200 total kcal. The patient has central venous access and reports no history of diabetes, hyperlipidemia, or egg allergy. The patient is not fluid-restricted. The PN formulation will be compounded as an individualized regimen using a single-bag, 24-hour infusion of a TNA. Determine the total PN volume and administration rate by calculating the macronutrient solution volumes required to provide the desired daily nutrients. The PN products used for this regimen are 10% CAA, 70% dextrose, and 30% IVLE.

1. Determine the daily IVLE calories and volume.
   - 2,200 kcal/day × 30%–40% of total calories as fat = 660 – 880 kcal/day
   - Choose 660 kcal to minimize IVLE calories; calculate 30% IVLE volume

     660 kcal ÷ 3 cal/mL 30% IVLE = X mL   X = 220 mL 30% IVLE

   - Calculate IVLE gram amount
     30 g/100 mL = X g/220 mL 30% IVLE   X = 66 g IVLE
2. Determine the appropriate volume of 70% dextrose to deliver the desired dextrose calories
   - Dextrose calories = Total kcal – IVLE kcal – Protein kcal
     = 2,200 kcal – 660 kcal IVLE – (4 kcal × 105 g CAA) = 1,120 kcal
   - Calculate required dextrose (grams):

     1,120 kcal ÷ 3.4 kcal/g dextrose = 329 g dextrose

   - Determine 70% dextrose volume
     70 g/100 mL = 329 g/X mL 70% dextrose;   X = 470 mL 70% dextrose
3. Determine the appropriate volume of 10% CAA
   10 g/100 mL = 105 g/X mL 10% CAA   X = 1,050 mL 10% CAA
4. Determine the TNA PN volume and administration rate
   - Calculate CAA/dextrose/IVLE volume:
     470 mL 70% dextrose + 1,050 mL 10% CAA + 220 mL 30% IVLE = 1,740 mL
   - Add 100-200 mL for additives:
     Total TNA volume = approximately 1,840-1,940 mL/day
   - Calculate the administration rate:
     1,840 to 1,940 mL/day ÷ 24 h = 77 to 81 mL/h; round up to 80 to 85 mL/h
5. Choose final TNA regimen and determine final concentrations of CAA, dextrose, and IVLE
   - Final TNA regimen
     105 g CAA/329 g dextrose/66 g IVLE in 1,920 mL/d to infuse at 80 mL/h
   - Calculate final concentrations of CAA, dextrose, and IVLE
     - 105 g CAA/1,920 mL = X g/100 mL   X = 5.5% CAA
     - 329 g dextrose/1,920 mL = X g/100 mL   X = 17.1% dextrose
     - 66 g IVLE/1,920 mL = X g/100 mL   X = 3.4% IVLE

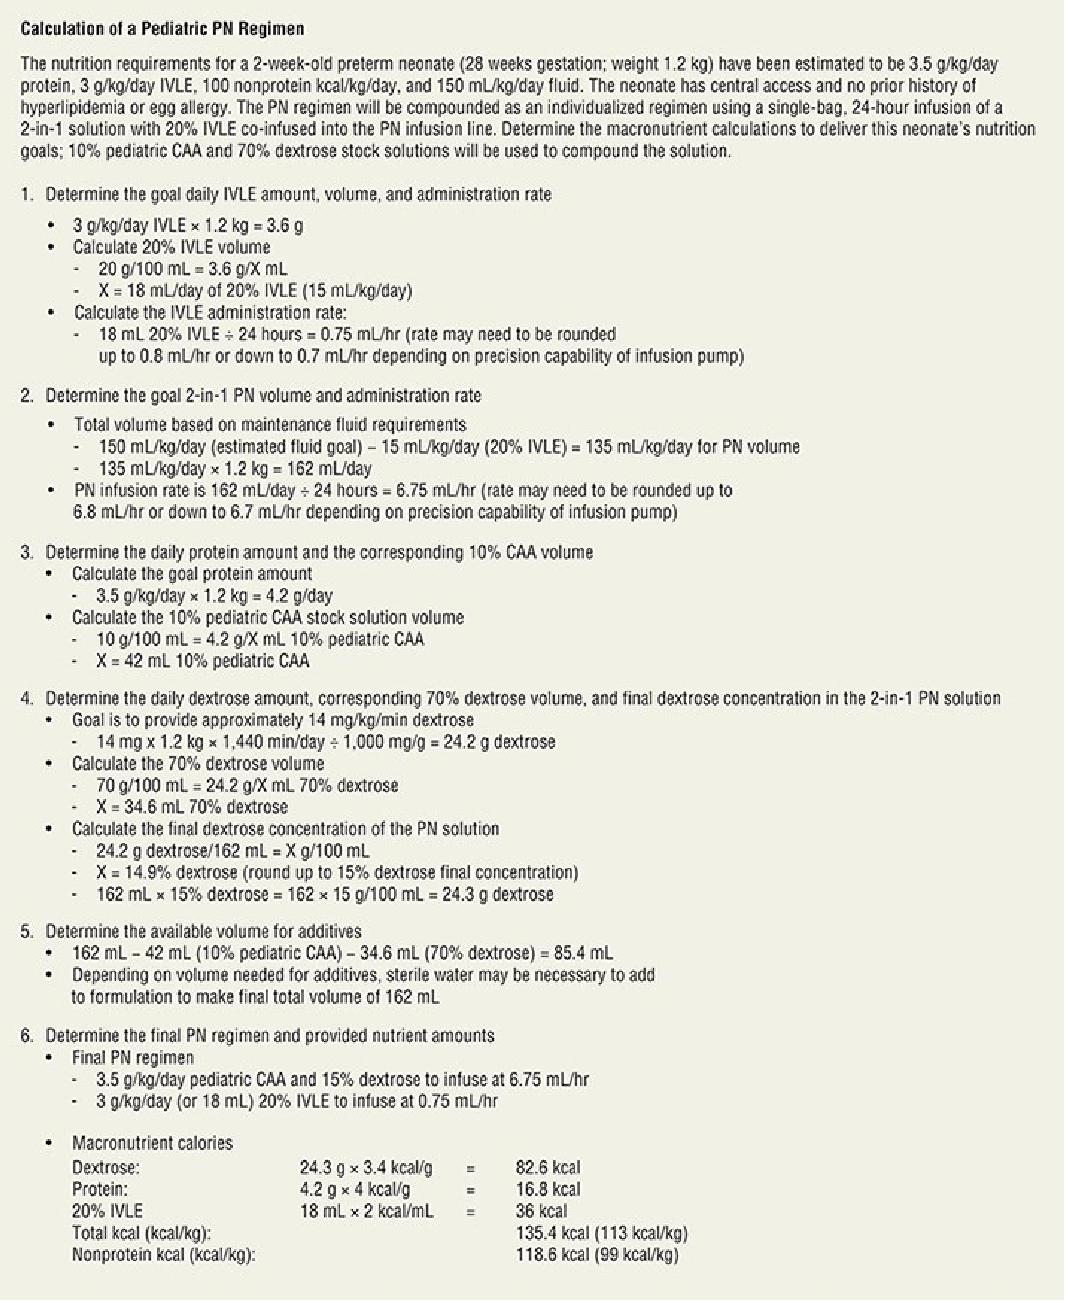
Several guidelines are available to help simplify calculation of a PN regimen after a patient's nutritional requirements have been decided. For example, adult patients receiving only PN therapy may need larger volumes of fluid to provide maintenance requirements and replace extrarenal losses. However, patients requiring other IV medication therapy may receive adequate fluid from an additional IV maintenance solution (eg, 0.45% NaCl in 5% dextrose) or co-infused medications (or both). Depending on individual institutional practices, maximally concentrating the PN admixture and using an inexpensive maintenance fluid to manage hydration may provide a cost-effective regimen that requires fewer adjustments. Another guideline that may be helpful in designing a PN regimen is to allow a volume of approximately 100 to 150 mL/L of base solution (~200-300 mL/day) for electrolytes and other additives. PN regimens for patients who require small amounts of additives, such as patients with kidney failure, may need further concentration.

Pediatric Parenteral Nutrition Solutions

Pediatric PN admixtures are typically ordered using an individualized approach because current safe clinical practice guidelines recommend nutrient intakes based on the patient's weight.[5] To simplify pediatric PN ordering, many institutions use a pediatric-specific PN order form that expresses daily nutrient amount based on weight. For example, protein and fat are ordered as grams per kilogram per day, dextrose as milligrams per kilogram per minute, and electrolytes as milliequivalents per kilogram per day. However, some institutions may order macronutrients by expressing the final concentration of each component in the solution. Current safe practice guidelines recommend ordering all PN ingredients based on weight as "amount per kilogram per day."[5] The PN bag label should accurately reflect the weight-based order as well. Calculations for determining a pediatric PN admixture are reviewed to illustrate fundamental concepts for ordering pediatric PN formulations (Fig. 165-2). Additional features of the pediatric PN label include the dosing weight, administration date and time, expiration date, infusion rate, and duration of infusion. Because infants and children generally receive daily maintenance fluid from the PN regimen, supplemental IV solutions are rarely needed. Pediatric PN may be provided as a two-in-one admixture or TNA. However, the TNA system is not recommended for compounding neonatal and infant PN because of ILE instability with the often needed higher calcium and phosphorus concentrations.[41,56] The ILE labeling guidelines for pediatric PN are similar to adult ILE labeling recommendations.

FIGURE 165-2

Calculation of a pediatric PN regimen. To convert to energy units of kilojoules, multiply values with kilocalories as the numerator (kcal, kcal/mL, kcal/kg, kcal/g) by 4.18 to give the corresponding value in kilojoules (kJ, kJ/mL, kJ/kg, kJ/g). (CAA, crystalline amino acids; ILE, lipid injectable emulsion.)



Calculation of a Pediatric PN Regimen

The nutrition requirements for a 2-week-old preterm neonate (28 weeks gestation; weight 1.2 kg) have been estimated to be 3.5 g/kg/day protein, 3 g/kg/day IVLE, 100 nonprotein kcal/kg/day, and 150 mL/kg/day fluid. The neonate has central access and no prior history of hyperlipidemia or egg allergy. The PN regimen will be compounded as an individualized regimen using a single-bag, 24-hour infusion of a 2-in-1 solution with 20% IVLE co-infused into the PN infusion line. Determine the macronutrient calculations to deliver this neonate's nutrition goals; 10% pediatric CAA and 70% dextrose stock solutions will be used to compound the solution.

1. Determine the goal daily IVLE amount, volume, and administration rate
   - 3 g/kg/day IVLE × 1.2 kg = 3.6 g
   - Calculate 20% IVLE volume
     - 20 g/100 mL = 3.6 g/X mL
     - X = 18 mL/day of 20% IVLE (15 mL/kg/day)
   - Calculate the IVLE administration rate:
     - 18 mL 20% IVLE ÷ 24 hours = 0.75 mL/hr (rate may need to be rounded up to 0.8 mL/hr or down to 0.7 mL/hr depending on precision capability of infusion pump)

2. Determine the goal 2-in-1 PN volume and administration rate
   - Total volume based on maintenance fluid requirements
     - 150 mL/kg/day (estimated fluid goal) – 15 mL/kg/day (20% IVLE) = 135 mL/kg/day for PN volume
     - 135 mL/kg/day × 1.2 kg = 162 mL/day
   - PN infusion rate is 162 mL/day ÷ 24 hours = 6.75 mL/hr (rate may need to be rounded up to 6.8 mL/hr or down to 6.7 mL/hr depending on precision capability of infusion pump)

3. Determine the daily protein amount and the corresponding 10% CAA volume
   - Calculate the goal protein amount
     - 3.5 g/kg/day × 1.2 kg = 4.2 g/day
   - Calculate the 10% pediatric CAA stock solution volume
     - 10 g/100 mL = 4.2 g/X mL 10% pediatric CAA
     - X = 42 mL 10% pediatric CAA

4. Determine the daily dextrose amount, corresponding 70% dextrose volume, and final dextrose concentration in the 2-in-1 PN solution
   - Goal is to provide approximately 14 mg/kg/min dextrose
     - 14 mg x 1.2 kg × 1,440 min/day ÷ 1,000 mg/g = 24.2 g dextrose
   - Calculate the 70% dextrose volume
     - 70 g/100 mL = 24.2 g/X mL 70% dextrose
     - X = 34.6 mL 70% dextrose
   - Calculate the final dextrose concentration of the PN solution
     - 24.2 g dextrose/162 mL = X g/100 mL
     - X = 14.9% dextrose (round up to 15% dextrose final concentration)
     - 162 mL × 15% dextrose = 162 × 15 g/100 mL = 24.3 g dextrose

5. Determine the available volume for additives
   - 162 mL – 42 mL (10% pediatric CAA) – 34.6 mL (70% dextrose) = 85.4 mL
   - Depending on volume needed for additives, sterile water may be necessary to add to formulation to make final total volume of 162 mL

6. Determine the final PN regimen and provided nutrient amounts
   - Final PN regimen
     - 3.5 g/kg/day pediatric CAA and 15% dextrose to infuse at 6.75 mL/hr
     - 3 g/kg/day (or 18 mL) 20% IVLE to infuse at 0.75 mL/hr
   - Macronutrient calories

Dextrose:	24.3 g × 3.4 kcal/g	=	82.6 kcal
Protein:	4.2 g × 4 kcal/g	=	16.8 kcal
20% IVLE	18 mL × 2 kcal/mL	=	36 kcal
Total kcal (kcal/kg):			135.4 kcal (113 kcal/kg)
Nonprotein kcal (kcal/kg):			118.6 kcal (99 kcal/kg)

Administration Techniques

PN admixtures should be administered with an infusion pump. The IV administration line for CAA-dextrose solutions should include a 1.2 μm inline filter to remove any particulate matter that may be present in the solution.[63] This filter size also removes *Candida albicans*. ILE's may be administered separately from the CAA-dextrose solution by co-infusion into the PN line. However, co-infused ILE should also be filtered with a 1.2 μm filter.[31–35,41,63] A single 1.2 μm filter may be placed below the Y-site of the IV administration line where the dextrose-amino acid admixture and the ILE co-infuse to simplify PN filtering practices.[63] TNA solutions should be filtered with a 1.2 μm filter placed as close to the IV catheter hub as possible.

INITIATING AND ADVANCING THE PARENTERAL NUTRITION INFUSION

Adult Parenteral Nutrition

The patient's nutrition status, current clinical status, history of glucose tolerance, and dextrose concentration in the formula will dictate the infusion rate at which the adult PN solution should be initiated. Stable patients with normal organ function and stable baseline serum glucose concentrations have demonstrated minimal effect on serum glucose concentrations when PN is abruptly initiated or discontinued.[5,64] However, another approach is to begin the PN infusion and increase the rate gradually over 12 to 24 hours to the desired rate. The infusion rate may likewise be reduced in a stepwise fashion, such as decreasing the rate by 50% for 1 hour before discontinuation.[5,64] This approach should prevent development of hyperglycemia and rebound hypoglycemia, respectively. Alternatively, the PN regimen may be initiated at the goal infusion rate but with a hypocaloric dextrose dose. The dextrose dose can be increased daily to the goal based on patient response. Tapered initiation and cessation should be considered for patients receiving intermittent subcutaneous regular insulin; patients with severe kidney or liver disease; and patients with other disease states who have an increased risk for development of hyperglycemia or hypoglycemia, such as severe diabetes mellitus or pancreatic malignancy.

The SO-ILE dose should not exceed 2.5 g/kg/day or 60% of total daily calories, lower doses of 1 g/kg/day not to exceed 30% of calories have been recommended to minimize negative effects associated with long-chain fatty acids.[12,31,35] Higher doses of mixed-oil ILE up to 2.5 g/day may be necessary to prevent EFAD in patients with larger energy requirements. Manufacturer's dosing and administration recommendations differ depending on the product.[31–35] However, co-infusion over 12 hours as a separate infusion with two-in-one admixtures and infusion over no longer than 24 hours in a TNA formulation is the best clinical strategy to promote ILE clearance and minimize risk of negative effects on infection control and pulmonary and immune function.[5]

The manufacturer's guidelines recommend initiating SO-ILE and SMOF ILE with a test dose of 0.5 to 1 mL/min for the first 15 to 30 minutes because of the potential for an immediate hypersensitivity reaction.[31,37] For most adult patients, this is probably not necessary because of the relatively low incidence and benign nature of acute adverse reactions. In addition, infusion over 12 to 24 hours eliminates the need for a test dose because the infusion rate is within the range of the recommended test dose rates. Appropriate electrolytes should be provided to patients with normal organ function based on standard nutrient ranges Adjustments may be necessary depending on the patient's clinical condition. Adults and children older than 11 years should receive daily amounts of trace elements and an adult vitamin formulation.

Pediatric Parenteral Nutrition

Pediatric PN solutions are typically initiated with a volume calculated to provide the patient's daily maintenance fluid requirements on the first day of therapy. Individual nutrient substrates are then advanced daily as tolerated with the goal PN regimen generally being achieved by day 3 of therapy. However, the PN formulation should be initiated with the goal of achieving the desired protein dose on day 1. The initial dextrose dose for older infants and children is based on their previous glucose tolerance. Although practices may vary, one approach is to start with 10% dextrose and advance the concentration in 5% increments daily, as tolerated, to goals of 10 to 14 mg/kg/min in infants, 8 to 10 mg/kg/min in children, or 5 to 6 mg/kg/min in adolescents.[16] Initial dextrose doses for premature infants should approximate fetal nutrient delivery rates of 5 to 6 mg/kg/min. Frequently, this results in a final PN dextrose concentration of 5% to 10%. The dextrose concentration for the neonatal PN should be advanced daily by 1% to 2.5% or by 2 to 4 mg/kg/min increments to a goal of 10 to 14 mg/kg/min (maximum, 14-18 mg/kg/min).[16] SO-ILE is usually initiated at 0.5 g/kg/day for neonates and 0.5 to 1 g/kg/day for infants and children and increased daily by 0.5 to 1 g/kg/day. Incremental increases of SO-ILE dose allow daily serum triglyceride evaluation and early detection of those with impaired fat clearance. The SO-ILE dose should not exceed 60% of total daily calories for neonates and 30% of total calories for children, and the maximum SO-ILE dose should not exceed 3 g/kg/day (approximately 30 kcal/kg/day [126 kJ/kg/day]) for infants and 2.5 g/kg/day for children.[16] The maximum dose for FO-ILE is 1 g/kg/day.[34] The best clinical strategy for minimizing the risk of adverse medication reactions associated with SO-ILE administration and promoting ILE clearance is to infuse SO-ILE over 20 to 24 hours, not exceeding 1 g/kg in 4 hours. FO-ILE may be infused over 8 to 12 hours.[34,41]

IV electrolytes, vitamins, and trace elements should be initiated on the first day of therapy and continued as a daily component of the PN solution.[5,16] Children younger than 11 years should receive a vitamin product formulated for pediatric patients. Two multivitamin dosing schemas may be used for infants and children.[16] One method recommends 2 mL/kg/day for infants weighing less than 2.5 kg (l5.5 lb) and 5 mL/day for infants and children weighing 2.5 kg (5.5 lb) or greater. The other suggests 30% of a vial (1.5 mL/day) for infants weighing less than 1 kg (2.2 lb), 65% of a vial (3.25 mL/day) for infants weighing 1 to 3 kg (2.2-6.6 lb), and 100% of the vial (5 mL/day) for children weighing more than 3 kg (6.6 lb) (up to 11 years of age). Adult injectable vitamin products should not be used for infants because of potential neurotoxicity from accumulation of polysorbate and propylene glycol preservatives. Dosage recommendations for the reformulated multiple trace element products approved for use in pediatric patients are 0.2 mL every other day for neonates weighing less than 0.6 kg and 0.3 mL/kg/day for neonates and infants at least 0.6 kg and less than 10 kg (maximum daily dose of 1 mL) using the product approved for pediatric patients less than 10 kg. The daily dose for the product approved for pediatric patients 10 kg and greater is 0.2 mL, 0.4 mL, 0.6 mL, or 0.8 mL (based on weight range). Children weighing 50 kg (110 lb) or greater should receive the adult dose of 1 mL daily. Weight-based doses of the multiple trace element products do not provide the recommended daily intake for all trace elements, so additional supplementation or individual dosing with single-entity products is necessary. Individualized dosing allows for dose adjustment based on serum trace element assessment, individual patient characteristics (eg, cholestasis, stool losses, wounds), and the provision of the recommended intake across the pediatric age spectrum from a single source for each trace element supplemented. And while the amounts of chromium and manganese are lower in the reformulated multiple trace element products, individualized dosing allows for the need to minimize or remove these trace elements in patients with evidence of accumulation. Pediatric patients receiving PN commonly transition from PN support to EN gradually, over a period of days to weeks, by decreasing the PN infusion rate while increasing the enteral intake. The PN infusion rate should be reduced for 1 to 2 hours before stopping the infusion for neonates and infants because of their immature counter-regulatory mechanisms that contribute to an increased risk for developing rebound hypoglycemia.[5] Blood glucose concentrations should be measured within 15 to 60 minutes after the PN infusion ends.

Continuous Versus Cyclic Infusions
